MARKUS LOHREY, University of Siegen, Germany

We show that a context-free grammar of size m that produces a single string w of length n (such a grammar is also called a string straight-line program) can be transformed in linear time into a context-free grammar for w of size $O(m)$, whose unique derivation tree has depth $O(\log n)$. This solves an open problem in the area of grammar-based compression, improves many results in this area, and greatly simplifies many existing constructions. Similar results are shown for two formalisms for grammar-based tree compression: top dags and forest straight-line programs. These balancing results can be all deduced from a single meta-theorem stating that the depth of an algebraic circuit over an algebra with a certain finite base property can be reduced to $O(\log n)$ with the cost of a constant multiplicative size increase. Here, n refers to the size of the unfolding (or unravelling) of the circuit. In particular, this results applies to standard arithmetic circuits over (noncommutative) semirings.

1 INTRODUCTION

Grammar-based string compression. In *grammar-based compression* a combinatorial object is compactly represented using a grammar of an appropriate type. Such a grammar can be up to exponentially smaller than the object itself. A well-studied example of this general idea is grammar-based string compression using context-free grammars that produce only one string, which are also known as *straight-line programs*. Since the term “straight-line programs” is used in the literature

for different kinds of objects (e.g., arithmetic straight-line programs), and we will also deal with different types of straight-line programs, we use the term **string straight-line program (SSLP)** for short. Grammar-based string compression is tightly related to dictionary-based compression: The famous LZ78 algorithm can be viewed as a particular grammar-based compressor, the number of phrases in the LZ77-factorization is a lower bound for the smallest SSLP for a string [36], and an LZ77-factorization of length m can be converted to an SSLP of size $O(m \cdot \log n)$ where n is the length of the string [11, 24, 26, 36]. For various other aspects of grammar-based string compression see References [11, 29].

Balancing string straight-line programs. The two important measures for an SSLP are size and depth. To define these measures, it is convenient to assume that all right-hand sides of the grammar have length two (as in Chomsky normal form). Then, the size $|\mathcal{G}|$ of an SSLP \mathcal{G} is the number of variables (nonterminals) of \mathcal{G} and the depth of \mathcal{G} ($\text{depth}(\mathcal{G})$ for short) is the depth of the unique derivation tree of \mathcal{G} . It is straightforward to show that any string s of length n can be produced by an SSLP of size $O(n)$ and depth $O(\log n)$. A more difficult problem is to balance a given SSLP: Assume that the SSLP \mathcal{G} produces a string of length n . Several authors have shown that one can restructure \mathcal{G} in time $O(|\mathcal{G}| \cdot \log n)$ into an equivalent SSLP \mathcal{H} of size $O(|\mathcal{G}| \cdot \log n)$ and depth $O(\log n)$ [11, 26, 36].

Finding SSLPs of small size and small depth is important in many algorithmic applications. A prominent example is the *random access problem for grammar-compressed strings*: For a given SSLP \mathcal{G} that produces the string s of length n and a given position $p \in [1, n]$ one wants to access the p th symbol in s . As observed in Reference [8] one can solve this problem in time $O(\text{depth}(\mathcal{G}))$ (assuming arithmetic operations on numbers from the interval $[0, n]$ use constant time). Combined with one of the known SSLP balancing procedures [11, 36] one obtains access time $O(\log n)$, but one has to pay with an increased SSLP size of $O(|\mathcal{G}| \cdot \log n)$. Using sophisticated data structures, the following result was shown in Reference [8].

THEOREM 1.1 (RANDOM ACCESS TO GRAMMAR-COMPRESSED STRINGS, CF. [8]). *From a given SSLP \mathcal{G} of size m that generates the string s of length n , one can construct in time $O(m)$ a data structure of size $O(m)$ (measured in words of bit length $\log n$) that allows to answer random access queries in time $O(\log n)$.*

Our main result for string straight-line programs states that SSLP balancing is in fact possible with a constant blow-up in size.

THEOREM 1.2. *Given an SSLP \mathcal{G} producing a string of length n one can construct in linear time an equivalent SSLP \mathcal{H} of size $O(|\mathcal{G}|)$ and depth $O(\log n)$.*

As a corollary, we obtain a very simple and clean proof of Theorem 1.1. We can also obtain an algorithm for the random access problem with running time $O(\log n / \log \log n)$ using $O(m \cdot \log^\epsilon n)$ words of bit length $\log n$; previously this bound was only shown for balanced SSLPs [2]. Section 2.4 contains a list of further applications of Theorem 1.2, which include the following problems on SSLP-compressed strings: rank and select queries [2], subsequence matching [3], computing Karp-Rabin fingerprints [6], computing runs, squares, and palindromes [23], real-time traversal [19, 33], and range-minimum queries [20]. In all these applications, we either improve existing results or significantly simplify existing proofs by replacing $\text{depth}(\mathcal{G})$ by $O(\log n)$ in time/space bounds.

Let us say a few words over the underlying computational model in Theorem 1.2. Our balancing procedure involves (simple) arithmetic on lengths, i.e., numbers of order n . Thus the linear running time can be achieved assuming that machine words have $\Omega(\log n)$ bits. Otherwise the running time increases by a multiplicative $\log n$ factor. Note that such an assumption is realistic and standard in the field, since machine words of bit length $\Omega(\log n)$ are needed, say, for indexing positions in the represented string. Furthermore, our procedure works in the pointer model regime.

Balancing forest straight-line programs and top dags. Grammar-based compression has been generalized from strings to ordered ranked node-labelled trees. In fact, the representation of a tree t by its smallest **directed acyclic graph (DAG)** is a form of grammar-based tree compression. This DAG is obtained by merging nodes where the same subtree of t is rooted. It can be seen as a regular tree grammar that produces only t . A drawback of DAG-compression is that the size of the DAG is lower-bounded by the height of the tree t . Hence, for deep narrow trees (like for instance caterpillar trees), the DAG-representation cannot achieve good compression. This can be overcome by representing a tree t by a linear context-free tree grammar that produces only t . Such grammars are also known as *tree straight-line programs* in the case of ranked trees [10, 31, 32] and *forest straight-line programs* in the case of unranked trees [16]. The latter are tightly related to *top dags* [4, 7, 13, 16, 22], which are another tree compression formalism, also akin to grammars. Our balancing technique works similarly for those types of compression.

THEOREM 1.3. *Given a top dag/forest straight-line program/tree straight-line program \mathcal{G} producing the tree t one can compute in time $O(|\mathcal{G}|)$ a top dag/forest straight-line program/tree straight-line program \mathcal{H} for t of size $O(|\mathcal{G}|)$ and depth $O(\log |t|)$.*

For top dags, this solves an open problem from Reference [7], where it was proved that from a tree t of size n , whose minimal DAG has size m (measured in number of edges in the DAG), one can construct in linear time a top dag for t of size $O(m \cdot \log n)$ and depth $O(\log n)$. It remained open whether one can get rid of the factor $\log n$ in the size bound. For the specific top dag constructed in Reference [7], it was shown in Reference [4] that the factor $\log n$ in the size bound $O(m \cdot \log n)$ cannot be avoided. However, our results yield another top dag of size $O(m)$ and depth $O(\log n)$. To see this note that one can easily convert the minimal DAG of t into a top dag of roughly the same size, which can then be balanced. This also gives an alternative proof of a result from Reference [13], according to which one can construct in linear time a top dag of size $O(n/\log_\sigma n)$ and depth $O(\log n)$ for a given tree of size n containing σ many different node labels.

Balancing circuits over algebras. Our balancing results for SSLPs, top dags, forests straight-line programs and tree straight-line programs are all instances of a general balancing result that applies to a large class of circuits over algebraic structures. To see the connection between circuits and straight-line programs, consider SSLPs as an example. An SSLP is the same thing as a bounded fan-in circuit over a free monoid. The circuit gates compute the concatenation of their inputs and correspond to the variables of the SSLP. In general, for any algebra one can define straight-line programs, which coincide with the classic notion of circuits.

The definition of a class of algebras, to which our general balancing technique applies, uses *unary linear term functions*, which were also used for instance in the context of efficient parallel evaluation of expression trees [34]. Fix an algebra \mathcal{A} (a set together with finitely many operations of possibly different arities). For some of our applications, we have to allow multi-sorted algebras that have several carrier sets (think for instance of a vector space, where the two carrier sets are an abelian group and a field of scalars). A unary linear term function is a unary function on \mathcal{A} that is computed by a term (or algebraic expression) that contains a single variable x (which stands for the function argument) and, moreover, x occurs exactly once in the term. For instance, a unary linear term function over a commutative ring is of the form $x \mapsto ax + b$ for ring elements a, b . A *subsumption base* for an algebra \mathcal{A} is, roughly speaking, a finite set $C(\mathcal{A})$ of unary linear term functions that are described by terms with parameters such that every unary linear term function can be obtained from one of the terms in $C(\mathcal{A})$ by instantiating the parameters. In the above example for a commutative ring the set $C(\mathcal{A})$ consists of the single term $ax + b$, where a and b are the parameters.

Our general balancing result needs one more concept, namely the *unfolded size* of a circuit \mathcal{G} . It can be conveniently defined as follows: We replace in \mathcal{G} every input gate by the number 1, and we

replace every internal gate by an addition gate. The unfolded size of \mathcal{G} is the value of this additive circuit. In other words, this is the size of the tree obtained by unravelling \mathcal{G} into a tree. Note that the size of this unfolding can be exponential in the circuit size. Now we can state the general balancing result in a slightly informal way (the precise statement can be found in Theorem 3.20).

THEOREM 1.4 (INFORMAL STATEMENT). *Let \mathcal{A} be a multi-sorted algebra with a finite number of operations (of arbitrary arity) such that \mathcal{A} has a finite subsumption base. Given a circuit \mathcal{G} over \mathcal{A} whose unfolded size is n , one can compute in time $O(|\mathcal{G}|)$ a circuit \mathcal{H} evaluating to the same element of \mathcal{A} such that $|\mathcal{H}| \in O(|\mathcal{G}|)$ and $\text{depth}(\mathcal{H}) \in O(\log n)$.*

Theorems 1.2 and 1.3 are immediate corollaries of Theorem 1.4. Theorem 1.4 can be also applied to not necessarily commutative semirings, as every semiring has a finite subsumption base. Hence, for every semiring circuit one can reduce with a linear size blow-up the depth to $O(\log n)$, where n is the size of the circuit unfolding.

Note that in the depth bound $O(\log n)$ in our balancing result for string straight-line programs (Theorem 1.2), n refers to the length of the produced string. A string straight-line program can be viewed as a circuit for a non-commutative semiring circuit that produces a single monomial (the symbols in the string correspond to the non-commuting variables). If one considers arbitrary circuits over non-commutative semirings (that produce a sum of more than one monomial), then depth reduction is not possible in general by a result of Kosaraju [27]. For circuits over commutative semirings depth reduction is possible by a seminal result of Valiant, Skyum, Berkowitz, and Rackoff [38]: For any commutative semiring, every circuit of size m and formal degree d can be transformed into an equivalent circuit of depth $O(\log m \log d)$ and size polynomial in m and d . This result led to many further investigations on depth reduction for bounded degree circuits over various classes of commutative as well as non-commutative semirings [1]. If one drops the restriction to bounded degree circuits, then depth reduction gets even harder. For general Boolean circuits, the best known result states that every Boolean circuit of size m is equivalent to a Boolean circuit of depth $O(m/\log m)$ [35].

Proof strategy. The proof of Theorem 1.2 consists of two main steps (the general result Theorem 1.4 is shown similarly). Take an SSLP \mathcal{G} for the string s of length n and let m be the size of \mathcal{G} . We consider the derivation tree t for \mathcal{G} ; it has size $O(n)$. The SSLP \mathcal{G} can be viewed as a DAG for t of size m . We decompose this DAG into node-disjoint paths such that each path from the root to a leaf intersects $O(\log n)$ paths from the decomposition (Section 2.1). Each path from the decomposition is then viewed as a string of integer-weighted symbols, where the weights are the lengths of the strings derived from nodes that branch off from the path. For this weighted string, we construct an SSLP of linear size that produces all suffixes of the path in a weight-balanced way (Section 2.2). Plugging these SSLPs together yields the final balanced SSLP.

Some of the concepts of our construction can be traced back to the area of parallel algorithms: The path decomposition for DAGs from Section 2.1 is related to the centroid decomposition of trees [12], where it is the key technique in several parallel algorithms on trees. Moreover, the SSLP of linear size that produces all suffixes of a weighted string with (Section 2.2) can be seen as a weight-balanced version of the optimal prefix sum algorithm.

For the general result Theorem 1.4, we need another ingredient: When the above construction is used for circuits over algebras, the corresponding procedure produces a tree straight-line program for the unfolding of the circuit. We show that if the underlying algebra \mathcal{A} has a finite subsumption base, then one can compute from a tree straight-line program an equivalent circuit over \mathcal{A} . Moreover, the size and depth of this circuit are linearly bounded in the size and depth of the tree straight-line program. This construction was used before for the special cases of semirings and regular expressions [15, 17].

2 PART I: BALANCING OF STRING STRAIGHT-LINE PROGRAMS

The goal of the first part of the article is to prove Theorem 1.2. This result can be also derived from our general balancing theorem (Theorem 1.4), which will be shown in the second part of the article (Section 3). The techniques that we introduce in part I will be also needed in Section 3. Moreover, we believe that it helps the reader to first see the simpler balancing procedure for string straight-line programs before going into the details of the general balancing result. Finally, the reader who is only interested in SSLP balancing can ignore part II completely.

We start with the afore-mentioned new decomposition technique for DAGs that we call symmetric centroid decomposition. The technical heart of our string balancing procedure is the linear-size SSLP that produces all suffixes of the path in a weight-balanced way (Section 2.2). Section 2.2 concludes the proof of Theorem 1.2, and Section 2.4 presents applications.

2.1 The Symmetric Centroid Decomposition of a DAG

We start with a new decomposition of a DAG into disjoint paths. We believe that this decomposition might have further applications. For trees, there exist several decompositions into disjoint paths with the additional property that every path from the root to a leaf only intersects a logarithmic number of paths from the decomposition; note that in general such decompositions allow empty paths, i.e., consisting of a single node only. Examples are the heavy path decomposition [21] and centroid decomposition [12]. These decompositions can be also defined for DAGs but a technical problem is that the resulting paths are no longer disjoint and form, in general, a subforest of the DAG, see, e.g., Reference [8].

Our new decomposition can be seen as a symmetric form of the centroid decomposition of Reference [12]. Consider a DAG $\mathcal{D} = (V, E)$ with node set V and the set of multi-edges E , i.e., E is a finite subset of $V \times \mathbb{N} \times V$ such that $(u, d, v) \in E$ implies that for every $1 \leq i < d$ there exists $v' \in V$ with $(u, i, v') \in E$. Intuitively, (u, d, v) is the d th outgoing edge of u . We assume that there is a single root node $r \in V$, i.e., r is the unique node with no incoming edges. Hence, all nodes are reachable from r . A path from $u \in V$ to $v \in V$ is a sequence of edges $(v_0, d_1, v_1), (v_1, d_2, v_2), \dots, (v_{p-1}, d_p, v_p)$ where $u = v_0$ and $v = v_p$. We also allow the empty path from u to u . With $\pi(u, v)$, we denote the number of paths from u to v , and for $V' \subseteq V$ let $\pi(u, V') = \sum_{v \in V'} \pi(u, v)$. Let $W \subseteq V$ be the set of sink nodes of \mathcal{D} , i.e., those nodes without outgoing edges, and let $n(\mathcal{D}) = \pi(r, W)$. This is the number of leaves in the tree obtained by unfolding \mathcal{D} into a tree. For a node $v \in V$ consider $(\pi(r, v), \pi(v, W))$: The number of paths leading from the root to v and the number of paths leading from v to all leaves. We assign to v the pair consisting of rounded (down) logarithms of those two numbers: $\lambda_{\mathcal{D}}(v) = (\lfloor \log_2 \pi(r, v) \rfloor, \lfloor \log_2 \pi(v, W) \rfloor)$. If $\lambda_{\mathcal{D}}(v) = (k, \ell)$, then $k, \ell \leq \lfloor \log_2 n(\mathcal{D}) \rfloor$, because $\pi(r, v)$ and $\pi(v, W)$ are both bounded by $n(\mathcal{D})$. Let us now define the edge set $E_{\text{scd}}(\mathcal{D})$ (**symmetric centroid decomposition (scd)**) as $E_{\text{scd}}(\mathcal{D}) = \{(u, i, v) \in E \mid \lambda_{\mathcal{D}}(u) = \lambda_{\mathcal{D}}(v)\}$. Figure 1 gives a detailed example of a symmetric centroid decomposition of a DAG.

LEMMA 2.1. *Let $\mathcal{D} = (V, E)$ be a DAG with $n = n(\mathcal{D})$. Then every node has at most one outgoing and at most one incoming edge from $E_{\text{scd}}(\mathcal{D})$. Furthermore, every path from the root r to a sink node contains at most $2 \log_2 n$ edges that do not belong to $E_{\text{scd}}(\mathcal{D})$.*

PROOF. Consider a node $v \in V$ with two different outgoing edges $(u, i, v), (u, j, w) \in E_{\text{scd}}(\mathcal{D})$. Hence, $\lambda_{\mathcal{D}}(u) = \lambda_{\mathcal{D}}(v) = \lambda_{\mathcal{D}}(w)$. Let $\lambda_{\mathcal{D}}(u) = (k, \ell)$. If W is the set of sinks, then we get $\pi(u, W) \geq \pi(v, W) + \pi(w, W)$ (since we consider paths of multi-edges, this inequality also holds for $v = w$). Without loss of generality assume that $\pi(w, W) \geq \pi(v, W)$ and thus $\pi(u, W) \geq 2\pi(v, W)$. We get

$$\lfloor \log_2 \pi(u, W) \rfloor \geq 1 + \lfloor \log_2 \pi(v, W) \rfloor = 1 + \lfloor \log_2 \pi(u, W) \rfloor,$$

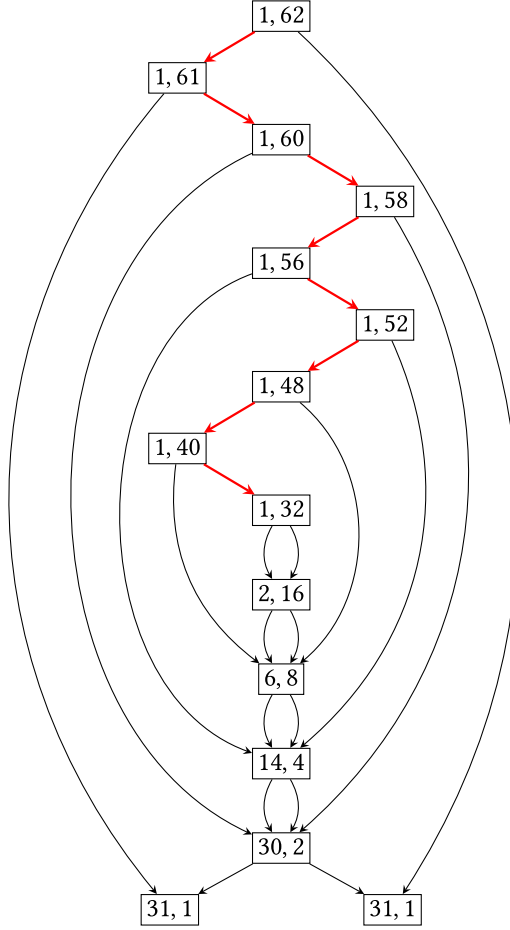

Fig. 1. A DAG and its symmetric centroid path decomposition. The numbers in a node v are the values $\pi(r, v)$, where r is the root, i.e., the number of incoming paths from r , and $\pi(v, W)$, where W consists of the two sink nodes, i.e., the number of paths from v to sinks. Edges that belong to a symmetric centroid path are drawn in red. Note that the nine topmost nodes form a symmetric centroid path, since $\lfloor \log_2 \pi(r, v) \rfloor = 0$ and $\lfloor \log_2 \pi(v, W) \rfloor = 5$ for each of these nodes. In this example the symmetric centroid path decomposition consists of one path of length 8 (number of edges); all other nodes form symmetric centroid paths of length zero, i.e., they are trivial.

where the last equality follows from $\lambda_{\mathcal{D}}(u) = \lambda_{\mathcal{D}}(v)$. This is a contradiction and proves the claim for outgoing edges. Incoming edges are treated similarly, this time using $\pi(r, v)$.

For the second claim of the Lemma, consider a path $(v_0, d_1, v_1), (v_1, d_2, v_2), \dots, (v_{p-1}, d_p, v_p)$, where v_0 is the root and v_p is a sink. Let $\lambda_{\mathcal{D}}(v_i) = (k_i, \ell_i)$, then $k_i \leq k_{i+1}$ and $\ell_i \geq \ell_{i+1}$ for all $0 \leq i \leq p-1$. Moreover, $k_0 = \ell_p = 0$ and $\ell_0, k_p \leq \lfloor \log_2 n \rfloor$. Consider now an edge $(v_i, d_i, v_{i+1}) \in E \setminus E_{\text{scd}}(\mathcal{D})$. Since $\lambda_{\mathcal{D}}(v_i) \neq \lambda_{\mathcal{D}}(v_{i+1})$, we have $k_i < k_{i+1}$ or $\ell_i > \ell_{i+1}$. Hence, there can be at most $2 \lfloor \log_2 n \rfloor \leq 2 \log_2 n$ edges from $E \setminus E_{\text{scd}}(\mathcal{D})$ on the path. \square

Lemma 2.1 implies that the subgraph $(V, E_{\text{scd}}(\mathcal{D}))$ is a disjoint union of possibly empty paths, called *symmetric centroid paths* of \mathcal{D} . It is straightforward to compute the edge set $E_{\text{scd}}(\mathcal{D})$ in time $O(|\mathcal{D}|)$, where $|\mathcal{D}|$ is defined as the number of edges of the DAG: By traversing \mathcal{D} in both

directions (from the root to the sinks and from the sinks to the root) one can compute all pairs $\lambda_{\mathcal{D}}(v)$ for $v \in V$ in linear time.

One can use Lemma 2.1 to simplify the original proof of Theorem 1.1 from Reference [8]: In Reference [8], the authors use the heavy-path decomposition of the derivation tree of an SSLP. In the SSLP (viewed as a DAG that defines the derivation tree), these heavy paths lead to a forest, called the heavy path forest [8]. The important property used in Reference [8] is the fact that any path from the root of the DAG to a sink node contains only $O(\log n)$ edges that do not belong to a heavy path, where n is the length of string produced by the SSLP. Using Lemma 2.1, one can replace this heavy path forest by the decomposition into symmetric centroid paths. The fact that the latter is a disjoint union of paths in the DAG simplifies the technical details in Reference [8] a lot. However, Theorem 1.1 follows directly from Theorem 1.2, see Section 2.4.

2.2 Straight-line Programs and Suffixes of Weighted Strings

Given an alphabet of symbols Σ , Σ^* denotes the set of all finite words over the alphabet Σ , including the empty word ε . The set of non-empty words is denoted by $\Sigma^+ = \Sigma^* \setminus \{\varepsilon\}$. The length of a word w is denoted with $|w|$.

Let Σ be a finite alphabet of terminal symbols. An SSLP over the alphabet Σ is a triple $\mathcal{G} = (\mathcal{V}, \rho, S)$, where \mathcal{V} is a finite set of variables, $S \in \mathcal{V}$ is the start variable, and $\rho : \mathcal{V} \rightarrow (\Sigma \cup \mathcal{V})^*$ (the right-hand side mapping) has the property that the binary relation $E(\mathcal{G}) = \{(X, Y) \in \mathcal{V} \times \mathcal{V} : Y \text{ occurs in } \rho(X)\}$ is acyclic. This allows to define for every variable $X \in \mathcal{V}$ a string $\llbracket X \rrbracket_{\mathcal{G}}$ as follows: If $\rho(X) = u_0 X_1 u_1 X_2 \cdots u_{n-1} X_n u_n$ with $u_0, u_1, \dots, u_n \in \Sigma^*$ and $X_1, \dots, X_n \in \mathcal{V}$, then $\llbracket X \rrbracket_{\mathcal{G}} = u_0 \llbracket X_1 \rrbracket_{\mathcal{G}} u_1 \llbracket X_2 \rrbracket_{\mathcal{G}} \cdots u_{n-1} \llbracket X_n \rrbracket_{\mathcal{G}} u_n$. We omit the subscript \mathcal{G} if \mathcal{G} is clear from the context. Finally, we define $\llbracket \mathcal{G} \rrbracket = \llbracket S \rrbracket$.

An SSLP \mathcal{G} can be seen as a context-free grammar that produces the single string $\llbracket \mathcal{G} \rrbracket$. Quite often, one assumes that all right-hand sides $\rho(X)$ are from $\Sigma \cup \mathcal{V}\mathcal{V}$. This corresponds to the Chomsky normal form. For a given SSLP \mathcal{G} with $\llbracket \mathcal{G} \rrbracket \neq \varepsilon$ one can construct in linear time an equivalent SSLP in Chomsky normal form [30, Proposition 3.8].

Fix an SSLP $\mathcal{G} = (\mathcal{V}, \rho, S)$. We define the size $|\mathcal{G}|$ of \mathcal{G} as $\sum_{X \in \mathcal{V}} |\rho(X)|$. Let d be the length of a longest path in the DAG $(\mathcal{V}, E(\mathcal{G}))$ and $r = \max\{|\rho(X)| : X \in \mathcal{V}\}$. We define the depth of \mathcal{G} as $\text{depth}(\mathcal{G}) = d \cdot \lceil \log_2 r \rceil$. Note that for an SSLP in Chomsky normal form, the definition of the depth simplifies to $\text{depth}(\mathcal{G}) = d$ and that these definitions ensure that depth and size only increase by fixed (multiplicative) constants when an SSLP is transformed into Chomsky normal form. This is exactly the purpose of this definition: Transforming into Chomsky normal form is a standard preprocessing and/or normalization procedure, and we want size and height to be roughly preserved during such a procedure. Last, observe that more refined notion of height, which takes into the account the rule sizes on particular paths, and not a bound on all of them, or the height of the actual Chomsky normal form (which is not unique) could be devised, but it is not needed for our purposes.

A *weighted string* is a string $s \in \Sigma^*$ equipped with a weight function $\|\cdot\| : \Sigma \rightarrow \mathbb{N} \setminus \{0\}$, which is extended to a homomorphism $\|\cdot\| : \Sigma^* \rightarrow \mathbb{N}$ by $\|a_1 a_2 \cdots a_n\| = \sum_{i=1}^n \|a_i\|$. If X is a variable in an SSLP \mathcal{G} , then we also write $\|X\|$ for the weight of the string $\llbracket X \rrbracket_{\mathcal{G}}$ derived from X . Moreover, when we speak of suffixes of a string, we always mean non-empty suffixes.

PROPOSITION 2.2. *For every non-empty weighted string s of length n one can construct in linear time an SSLP \mathcal{G} with the following properties:*

- \mathcal{G} contains at most $3n$ variables,
- all right-hand sides of \mathcal{G} have length at most 4,
- \mathcal{G} contains suffix variables S_1, \dots, S_n producing all suffixes of s , and

- every path from S_i to some terminal symbol a in the derivation tree of \mathcal{G} has length at most $3 + 2(\log_2 \|S_i\| - \log_2 \|a\|)$.

Before moving to the proof, let us explain the intuition behind the definition and statement: The intended usage of the weight is that a letter a with weight $\|a\| > 1$ is in fact a variable that has its separate SSLP \mathcal{A} , in which it derives a string of length $\|a\|$, i.e., $\llbracket a \rrbracket_{\mathcal{A}} = \|a\|$: In our constructions, we will compose several SLPs and symbols treated as letters in one SSLP are the starting variables in the other. The last condition of Proposition 2.2 fits well into this understanding: When we compose several SSLPs, then a becomes a variable deriving string of length $\|a\|$. Then several estimation of the form $3 + 2(\log_2 \|S_i\| - \log_2 \|a\|)$, $3 + 2(\log_2 \|a\| - \log_2 \|b\|)$, \dots are added together and they form a telescopic sum, so in the end we are left with $2(\log \|S_i\| - 0)$, which is logarithmic in the length of the word derived by S_i , as desired (there are also the sums of 3s, but those are estimated separately).

PROOF. First, the presented algorithm never uses the fact that some letters of s may be equal. Thus it is more convenient to assume that letters in s are pairwise different—in this way the path from a variable S_i to a terminal symbol a in the last condition is defined uniquely.

For the sake of an inductive proof, the constructed SSLP will satisfy a slightly stronger and more technical variant of the last condition: Every path from S_i to some terminal symbol a in the derivation tree of \mathcal{G} has length at most $1 + 2(\lceil \log_2 \|S_i\| \rceil - \log_2 \|a\|)$. The trivial estimation $\lceil \log_2 \|S_i\| \rceil \leq 1 + \log_2 \|S_i\|$ then yields the announced variant.

We first show how to construct \mathcal{G} with the desired properties and then prove that the construction can be done in linear time.

The case $n = 1$ is trivial. Now assume that $n \geq 2$ and let

$$s = a_1 \cdots a_k c b_1 \cdots b_m,$$

where $cb_1 \cdots b_m$ is the shortest suffix of s such that $\lceil \log_2 \|cb_1 \cdots b_m\| \rceil = \lceil \log_2 \|s\| \rceil$. Clearly such a suffix exists (in the extreme cases it is the entire string s or a single letter). Note that

$$\lceil \log_2 \|cb_1 \cdots b_m\| \rceil = \lceil \log_2 \|a_i \cdots a_k cb_1 \cdots b_m\| \rceil \quad (1)$$

for $1 \leq i \leq k + 1$. Moreover, the following inequalities hold:

$$\lceil \log_2 \|cb_1 \cdots b_m\| \rceil \geq \lceil \log_2 \|b_1 \cdots b_m\| \rceil + 1, \quad (2)$$

$$\lceil \log_2 \|cb_1 \cdots b_m\| \rceil \geq \lceil \log_2 \|a_1 \cdots a_k\| \rceil + 1, \quad (3)$$

(here, we define $\log_2(0) = -\infty$). The former is clear from the definition of $cb_1 \cdots b_m$, as $b_1 \cdots b_m$ satisfies $\lceil \log_2 \|b_1 \cdots b_m\| \rceil < \lceil \log_2 \|s\| \rceil = \lceil \log_2 \|cb_1 \cdots b_m\| \rceil$. If Equation (3) does not hold, then both $a_1 \cdots a_k$ and $cb_1 \cdots b_m$ have weights strictly more than $2^{\lceil \log_2 \|s\| \rceil - 1}$ and so their concatenation s has weight strictly more than $2^{\lceil \log_2 \|s\| \rceil} \geq \|s\|$, which is a contradiction.

Recall that the symbols $a_1, \dots, a_k, c, b_1, \dots, b_m$ are pairwise different by the convention from the first paragraph of the proof.

For $b_1 \cdots b_m$, we make a recursive call (if $m = 0$, then we do nothing at this step) and include the produced SSLP in the output SSLP \mathcal{G} . Let V_1, V_2, \dots, V_m be the variables such that

$$\llbracket V_i \rrbracket_{\mathcal{G}} = b_i \cdots b_m.$$

By the inductive assumption, every path $V_i \xrightarrow{*} b_j$ in the derivation tree has length at most

$$1 + 2\lceil \log_2 \|V_i\| \rceil - 2\log_2 \|a_j\|.$$

Add a variable V_0 with right-hand side cV_1 (or c if $m = 0$), which derives the suffix $cb_1 \cdots b_m$. The path from V_0 to c in the derivation tree has length 1, which is fine, and the path $V_0 \xrightarrow{*} a_j$ is one larger than the path $V_1 \xrightarrow{*} a_j$ and hence has length at most

$$1 + 1 + 2\lceil \log_2 \|V_1\| \rceil - 2\log_2 \|a_j\| \leq 2\lceil \log_2 \|V_0\| \rceil - 2\log_2 \|a_j\|,$$

as $1 + \lceil \log_2 \|V_1\| \rceil \leq \lceil \log_2 \|V_0\| \rceil$ by Equation (2).

Next, we decompose the prefix $a_1 \cdots a_k$ into $\lfloor k/2 \rfloor$ many blocks of length two and, when k is odd, one block of length 1, consisting of a_k . We add to the output SSLP \mathcal{G} new variables $X_1, \dots, X_{\lfloor k/2 \rfloor}$ and define their right-hand sides by

$$\rho(X_i) = a_{2i-1}a_{2i}.$$

The number of variables in \mathcal{G} is $\lfloor k/2 \rfloor$. For ease of presentation, when k is odd, define $X_{\lfloor k/2 \rfloor} = a_k$, this is not a new variable, rather just a notational convention to streamline the presentation. Note that for even k we have $\lfloor k/2 \rfloor = \lfloor k/2 \rfloor$ and in this case $X_{\lfloor k/2 \rfloor}$ is already defined. Viewing $X_1 \cdots X_{\lfloor k/2 \rfloor}$ as a weighted string of length $\lfloor k/2 \rfloor$ over the alphabet $\{X_1, \dots, X_{\lfloor k/2 \rfloor}\}$, we obtain inductively an SSLP \mathcal{G}_X with at most $3\lfloor k/2 \rfloor$ variables and right-hand sides of length at most 4 (if $k = 0$, then we do nothing at this step). Moreover, \mathcal{G}_X contains variables $U_1, U_2, \dots, U_{\lfloor k/2 \rfloor}$ with

$$\llbracket U_i \rrbracket_{\mathcal{G}_X} = X_i X_{i+1} \cdots X_{\lfloor k/2 \rfloor},$$

such that any path of the form $U_i \xrightarrow{*} X_j$ in the derivation tree of \mathcal{G}_X has length at most

$$1 + 2\lceil \log_2 \|U_i\| \rceil - 2\log_2 \|X_j\|.$$

By adding all variables and right-hand side definitions from \mathcal{G}_X to \mathcal{G} (where all symbols X_i are variables, except $X_{\lfloor k/2 \rfloor}$ when k is odd, in which case $X_{\lfloor k/2 \rfloor} = a_k$), we obtain

$$\llbracket U_i \rrbracket_{\mathcal{G}} = a_{2i-1}a_{2i} \cdots a_k$$

for all $1 \leq i \leq \lfloor k/2 \rfloor$. Any path $U_i \xrightarrow{*} a_j$ in the derivation tree of \mathcal{G} has length at most

$$2 + 2\lceil \log_2 \|U_i\| \rceil - 2\log_2 \|a_j\|. \quad (4)$$

Now, every suffix of s that includes some letter of $a_1 \cdots a_k$ (note that we already have variables for all other suffixes) can be defined by a right-hand side of the form $U_i c V_1$ or $a_{2i-2} U_i c V_1$ ($U_i c$ or $a_{2i-2} U_i c$ if $m = 0$). As in the statement of the lemma, denote those variables by S_1, \dots, S_k . Let us next verify the condition on the path lengths for derivations from those variables. All paths $S_i \xrightarrow{*} c$ have length one. Now consider a path $S_i \xrightarrow{*} a_j$. If the path has length one, then we are done. Otherwise, the path must be of the form $S_i \rightarrow U_l \xrightarrow{*} a_j$. Therefore, by Equation (4) the path length is at most

$$\begin{aligned} 3 + 2\lceil \log_2 \|U_l\| \rceil - 2\log_2 \|a_j\| &\leq 3 + 2\lceil \log_2 \|U_1\| \rceil - 2\log_2 \|a_j\| \\ &= 3 + 2\lceil \log_2 \|a_1 \cdots a_k\| \rceil - 2\log_2 \|a_j\| \\ &\leq 1 + 2\lceil \log_2 \|cb_1 \cdots b_m\| \rceil - 2\log_2 \|a_j\| \\ &= 1 + 2\lceil \log_2 \|S_i\| \rceil - 2\log_2 \|a_j\|, \end{aligned}$$

where the second inequality follows from Equation (3) and the equality at the end follows from Equation (1).

Paths of the form $S_i \xrightarrow{*} b_j$ can be treated similarly: They are of the form $S_i \rightarrow V_1 \xrightarrow{*} b_j$, where the path $V_1 \xrightarrow{*} b_j$ is of length at most $1 + 2\lceil \log_2 \|V_1\| \rceil - 2\log_2 \|a_j\|$ by the inductive assumption.

Thus, the whole path is of length at most

$$\begin{aligned} 2 + 2\lceil \log_2 \|V_1\| \rceil - 2\log_2 \|b_j\| &\leq 2\lceil \log_2 \|cb_1 \cdots b_m\| \rceil - 2\log_2 \|b_j\| \\ &= 2\lceil \log_2 \|S_i\| \rceil - 2\log_2 \|b_j\|, \end{aligned}$$

which follows from Equation (2) and Equation (1).

The SSLP \mathcal{G} consists of $\lfloor k/2 \rfloor$ variables X_i , $3(\lceil k/2 \rceil)$ variables from the recursive call for the weighted string $X_1 \cdots X_{\lceil k/2 \rceil}$, $3m = 3(n - k - 1)$ variables from the recursive call for $b_1 \cdots b_m$, and $1 + k$ new suffix variables for suffixes beginning at $a_1 \cdots a_k c$ (note that those beginning at $b_1 \cdots b_m$ are taken care of by the recursive call). Therefore \mathcal{G} contains at most

$$\lfloor k/2 \rfloor + 3\lceil k/2 \rceil + 3(n - k - 1) + 1 + k = 3n + 2\lceil k/2 \rceil - k - 2 < 3n$$

variables. Also note that all right-hand sides of \mathcal{G} have length at most four.

It remains to show that the construction works in linear time. To this end, we need a small trick: We assume that when the algorithm is called on s , we supply the algorithm with the value $\|s\|$. More formally, the main algorithm applied to a string s computes $\|s\|$ in linear time by going through s and adding weights. Then it calls a subprocedure $\text{main}'(s, \|s\|)$, which performs the actions described above. To find the appropriate symbol c , main' computes the weights of consecutive prefixes $s_1 s_2 \cdots s_i$, until it finds the first such that $\lceil \log_2 \|s\| \rceil > \lceil \log_2 (\|s\| - \|s_1 \cdots s_i\|) \rceil$. Then $k = i - 1$ and so $a_1 \cdots a_k = s_1 \cdots s_{i-1}$, $c = s_i$, $b_1 \cdots b_m = s_{i+1} \cdots s_{|s|}$. Moreover, we can compute $\|a_1 \cdots a_k\|$ and $\|b_1 \cdots b_m\|$ for the recursive calls of main' in constant time.

Let $T(n)$ be the running time of main' on a word of length n . Then all operations of main' , except the recursive calls, take at most $\alpha(k + 1)$ time for some constant $\alpha \geq 1$, where s is represented as $a_1 \cdots a_k c b_1 \cdots b_m$. Thus $T(n)$ satisfies $T(1) = 1$ and

$$T(n) = T(\lceil k/2 \rceil) + T(n - k - 1) + \alpha(k + 1).$$

We claim that $T(n) \leq 2\alpha n$. This is true for $n = 1$, and inductively for $n \geq 2$ we get

$$\begin{aligned} T(n) &\leq 2\alpha(\lceil k/2 \rceil) + 2\alpha(n - k - 1) + \alpha(k + 1) \\ &\leq 2\alpha \frac{k + 1}{2} + 2\alpha n - \alpha(k + 1) \\ &= 2\alpha n. \end{aligned}$$

This concludes the proof of the lemma. \square

2.3 Proof of Theorem 1.2

We now prove Theorem 1.2. Let $\mathcal{G} = (\mathcal{V}, \rho_{\mathcal{G}}, S)$. Without loss of generality we can assume that \mathcal{G} is in Chomsky normal form (the case that $\|G\| = \varepsilon$ is trivial). Note that the graph $(\mathcal{V}, E(\mathcal{G}))$ is a DAG. We can assume that every variable is reachable from the start variable S . Consider a variable X with $\rho_{\mathcal{G}}(X) = YZ$. Then X has the two outgoing edges (X, Y) and (X, Z) in $(\mathcal{V}, E(\mathcal{G}))$. We replace these two edges by the triples $(X, 1, Y)$ and $(X, 2, Z)$. Hence, $\mathcal{D} := (\mathcal{V}, E(\mathcal{G}))$ becomes a DAG with multi-edges (triples from $\mathcal{V} \times \{1, 2\} \times \mathcal{V}$). Figure 2 shows the DAG \mathcal{D} for an example SSLP; it is the same DAG as in Figure 1. The right-hand sides for the two sink variables X_{13} and X_{14} are terminal symbols (the concrete terminals are not relevant for us). The start variable S is X_0 .

We define for every $X \in \mathcal{V}$ the weight $\|X\|$ as the length of the string $\llbracket X \rrbracket_{\mathcal{G}}$. Moreover, for a string $w = X_1 X_2 \cdots X_n$ we define the weight $\|w\| = \sum_{i=1}^n \|X_i\|$. Note that $\|S\| = n$ is the length of the derived string $\llbracket \mathcal{G} \rrbracket$ and that this also the value $n(\mathcal{D})$ defined in Section 2.1.

We compute in linear time the edges from symmetric centroid decomposition of the DAG \mathcal{D} , see Lemma 2.1. In Figure 2 these are the red edges. The weights $\|X_i\|$ of the variables are written

Fig. 2. The DAG for an SSLP (it is the the same DAG as in Figure 1). The only non-trivial symmetric centroid path is drawn in red, as in Figure 1. Each node is annotated with the length of the derived string. The blue edges are the left edges of nodes whose right edges are on the symmetric centroid path (i.e., are red), similarly green edges are the right edges such that the corresponding left edges are on the symmetric centroid path. All other edges are black. If a node has an outgoing black edge, then both its outgoing edges are black and this node is the last node on some symmetric centroid path (this includes the case, when it is the only node on the path, i.e., when the path is trivial). Using the notation from the proof of Theorem 1.2, the node X_{10} is both X'_7 and X'_8 , as there are edges outside the centroid path from X_6 and X_7 to X_{10} .

next to the corresponding nodes; these weights can be found as the second components in Figure 1. Hence, we have $\|X_0\| = 62$, $\|X_1\| = 61$, $\|X_2\| = 60$, $\|X_3\| = 58$, and so on.

Consider a symmetric centroid path

$$(X_0, d_0, X_1), (X_1, d_1, X_2), \dots, (X_{p-1}, d_{p-1}, X_p) \quad (5)$$

in \mathcal{D} , where all X_i belong to \mathcal{V} and $d_i \in \{1, 2\}$. Thus, for all $0 \leq i \leq p-1$, the right-hand side of X_i in \mathcal{G} has the form $\rho_{\mathcal{G}}(X_i) = X_{i+1}X'_{i+1}$ (if $d_i = 1$) or $\rho_{\mathcal{G}}(X_i) = X'_{i+1}X_{i+1}$ (if $d_i = 2$) for some $X'_{i+1} \in \mathcal{V}$. Note that we can have $X'_i = X'_j$ for $i \neq j$, this happens for instance on Figure 2, it can also happen that $X_{i'} = X_j$ for $j > i$. The right-hand side $\rho_{\mathcal{G}}(X_p)$ belongs to $\Sigma \cup \mathcal{V}\mathcal{V}$. Note that

the variables X'_i ($1 \leq i \leq p$) and the variables in $\rho_{\mathcal{G}}(X_p)$ (if they exist) belong to other symmetric centroid paths. We will introduce $O(p)$ many variables in the SSLP \mathcal{H} to be constructed. Moreover, all right-hand sides of \mathcal{H} have length at most four. By summing over all symmetric centroid paths, this yields the size bound $O(|\mathcal{G}|)$ for \mathcal{H} .

We now define the right-hand sides of the variables X_0, \dots, X_p in \mathcal{H} . We write $\rho_{\mathcal{H}}$ for the right-hand side mapping of \mathcal{H} . For X_p , we set $\rho_{\mathcal{H}}(X_p) = \rho_{\mathcal{G}}(X_p)$. For the variables X_0, \dots, X_{p-1} we have to “accelerate” the derivation somehow to get the depth bound $O(\log n)$ at the end. For this, we apply Proposition 2.2. Let $L_1 \dots L_s$ be the subsequence obtained from $X'_1 X'_2 \dots X'_p$ by keeping only those X'_i with $d_{i-1} = 2$ for $i = 1, \dots, p$ and let $R_1 \dots R_t$ be the subsequence obtained from the reversed sequence $X'_p X'_{p-1} \dots X'_1$ by keeping only those X'_i with $d_{i-1} = 1$ for $i = p, \dots, 1$. Take for instance the red symmetric centroid path consisting of the nodes X_0, X_1, \dots, X_8 (hence, $p = 8$) from our running example in Figure 2. We have $L_1 \dots L_s = X_{13} X_{12} X_{11} X_{10}$ (the target nodes of the blue edges) and $R_1 \dots R_t = X_{10} X_{11} X_{12} X_{14}$ (the target nodes of the green edges).

Note that every string $\llbracket X_i \rrbracket$ ($0 \leq i \leq p-1$) can be derived in \mathcal{G} from a word $w_\ell X_p w_r$, where w_ℓ is a suffix of $L_1 \dots L_s$ and w_r is a prefix of $R_1 \dots R_t$. For instance, $\llbracket X_2 \rrbracket$ can be derived from $(X_{12} X_{11} X_{10}) X_8 (X_{10} X_{11} X_{12})$ in our running example, so $w_\ell = X_{12} X_{11} X_{10}$ and $w_r = X_{10} X_{11} X_{12}$. We now apply Proposition 2.2 to the sequence $L_1 \dots L_s$ to get an SSLP \mathcal{G}_ℓ of size $O(s) \leq O(p)$ that contains variables S_1, \dots, S_s for the non-empty suffixes of $L_1 \dots L_s$. Moreover, every path from a variable S_i to some L_j in the derivation tree has length at most $3 + 2 \log_2 \|S_i\| - 2 \log_2 \|L_j\|$, where $\|S_i\|$ is the weight of $\llbracket S_i \rrbracket_{\mathcal{G}_\ell}$. Analogously, we obtain an SSLP \mathcal{G}_r of size $O(t) \leq O(p)$ that contains variables P_1, \dots, P_t for the non-empty prefixes of $R_1 \dots R_t$. Moreover, every path from a variable P_i to some R_j in the derivation tree has length at most $3 + 2 \log_2 \|P_i\| - 2 \log_2 \|R_j\|$. We can then define every right-hand side $\rho_{\mathcal{H}}(X_i)$ as $S_j X_p P_k$, $X_p P_k$, $S_j X_p$, or X_p for suitable j and k . Moreover, we add all variables and right-hand side definitions of \mathcal{G}_ℓ and \mathcal{G}_r to \mathcal{H} .

We make the above construction for all symmetric centroid paths of the DAG \mathcal{D} . This concludes the construction of \mathcal{H} . In our running example we set $\rho_{\mathcal{H}}(X_i) = \rho_{\mathcal{G}}(X_i)$ for $8 \leq i \leq 14$. Since we introduce $O(p)$ many variables for every symmetric centroid path of length p and all right-hand sides of \mathcal{H} have length at most four, we obtain the size bound $O(|\mathcal{G}|)$ for \mathcal{H} .

It remains to show that the depth of the SSLP \mathcal{H} is $O(\log n)$. Let us first consider the symmetric centroid path (5) and a path in the derivation tree of \mathcal{H} from a variable X_i ($0 \leq i \leq p$) to a variable Y , where Y is

- (a) a variable in $\rho_{\mathcal{G}}(X_p) = \rho_{\mathcal{H}}(X_p)$ or
- (b) a variable X'_j for some $i < j \leq p$.

In case (a), the path $X_i \xrightarrow{*} Y$ has length at most two. In case (b) the path $X_i \xrightarrow{*} Y$ is of the form $X_i \xrightarrow{*} S_k \xrightarrow{*} X'_j = Y$ or $X_i \xrightarrow{*} P_k \xrightarrow{*} X'_j = Y$. Here, $S_k \xrightarrow{*} X'_j$ (respectively, $P_k \xrightarrow{*} X'_j$) is a path in \mathcal{G}_ℓ (respectively, \mathcal{G}_r) and therefore has length at most $3 + 2 \log_2 \|S_k\| - 2 \log_2 \|Y\|$ (respectively, $3 + 2 \log_2 \|P_k\| - 2 \log_2 \|Y\|$). In both cases, we can bound the length of the path $X_i \xrightarrow{*} Y$ by $4 + 2 \log_2 \|X_i\| - 2 \log_2 \|Y\|$.

Consider a maximal path in the derivation tree of \mathcal{H} that starts in the root S and ends in a leaf. We can factorize this path as

$$S = X_0 \xrightarrow{*} X_1 \xrightarrow{*} X_2 \xrightarrow{*} \dots \xrightarrow{*} X_k, \quad (6)$$

where all variables X_i belong to the original SSLP and every subpath $X_i \xrightarrow{*} X_{i+1}$ is of the form $X_i \xrightarrow{*} Y$ considered in the previous paragraph; note that X_i in general is not a parent of X_{i+1} , which is the case in the running example of Figure 2. The right-hand side of X_k is a single symbol

from Σ . In the DAG \mathcal{D} , we have a corresponding path $X_i \xrightarrow{*} X_{i+1}$, which is contained in a single symmetric centroid path except for the last edge leading to X_{i+1} . By the above consideration, the length of the path (6) is bounded by

$$\sum_{i=0}^{k-1} (4 + 2 \log_2 \|X_i\| - 2 \log_2 \|X_{i+1}\|) \leq 4k + 2 \log_2 \|S\| = 4k + 2 \log_2 n.$$

By the second claim of Lemma 2.1, we have $k \leq 2 \log_2 n$, which shows that the length of the path (6) is bounded by $10 \log_2 n$. \square

2.4 Applications of Theorem 1.2

There are several algorithmic applications of Theorem 1.2 with always the same idea: Let \mathcal{G} be an SSLP of size m for a string s of length n . In many algorithms for SSLP-compressed strings the running time or space consumption depends on $\text{depth}(\mathcal{G})$, which can be m in the worst case. Theorem 1.2 shows that we can replace $\text{depth}(\mathcal{G})$ by $O(\log n)$. This is the best we can hope for, since $\text{depth}(\mathcal{G}) \geq \Omega(\log n)$ for every SSLP \mathcal{G} . Moreover, SSLPs that are produced by practical grammar-based compressors (e.g., LZ78 or RePair) are in general unbalanced in the sense that $\text{depth}(\mathcal{G}) \geq \omega(\log n)$.

The time bounds in the following results refer to the RAM model, where arithmetic operations on numbers from the interval $[0, n]$ need time $O(1)$. The size of a data structure is measured in the number of words of bit length $\log_2 n$.

As a first application of Theorem 1.2, we can present a very simple new proof of Theorem 1.1 (random access for grammar-compressed strings) based on the folklore random access algorithm that works in time $O(\text{depth}(\mathcal{G}))$.

PROOF OF THEOREM 1.1 Using Theorem 1.2, we compute in time $O(m)$ an equivalent SSLP \mathcal{H} for s of size $O(m)$ and depth $O(\log n)$. By a single pass over \mathcal{H} , we compute for every variable X of \mathcal{H} the length of the word $\llbracket X \rrbracket$. Using these lengths one can descend in the derivation tree $\llbracket \mathcal{H} \rrbracket$ from the root to the i th leaf node (which is labelled with the i th symbol of s) in time $O(\text{depth}(\mathcal{H})) \leq O(\log n)$. \square

Remark 2.3. It is easy to see that the balancing algorithm from Theorem 1.2 can be implemented on a pointer machine, see Reference [37] for a discussion of the pointer machine model. This yields a pointer machine implementation of the random access data structure from Theorem 1.1. In contrast, the random access data structure from Reference [8] needs the RAM model (for the pointer machine model only preprocessing time and size $O(m \cdot \alpha_k(m))$ for any fixed k , where α_k is the k th inverse Ackermann function, is shown in Reference [8]). Recently, the $O(m)$ -space data structure from Reference [8] has been modified in Reference [5] so that it can be implemented on a pointer machine as well.

Using fusion trees [14] one can improve the time bound in Theorem 1.1 to $O(\log n / \log \log n)$ at the cost of an additional factor of $O(\log^\epsilon n)$ in the size bound. The following result has been shown in Reference [2, Theorem 2] under the assumption that the input SSLP has depth $O(\log n)$. We can enforce this bound with Theorem 1.2.

COROLLARY 2.4. *Fix an arbitrary constant $\epsilon > 0$. From a given SSLP \mathcal{G} of size m such that the string $s = \llbracket \mathcal{G} \rrbracket$ has length n , one can construct in time $O(m \cdot \log^\epsilon n)$ a data structure of size $O(m \cdot \log^\epsilon n)$ that allows to answer random access queries in time $O(\log n / \log \log n)$.*

PROOF. The proof is exactly the same as for Reference [2, Theorem 2]. There, the authors have to assume that the input SSLP has depth $O(\log n)$, which we can enforce by Theorem 1.2. Roughly

speaking, the idea in Reference [2] is to reduce the depth of the SSLP to $O(\log n / \log \log n)$ by expanding right-hand sides to length $O(\log^\epsilon n)$. Then for each right-hand side a fusion tree is constructed, which allows to spend constant time at each variable during the navigation to the i th symbol.

Let us also remark that the size bound for the computed data structure in Reference [2] is given in bits, which yields $O(m \cdot \log^{1+\epsilon} n)$ bits, since numbers from $[0, n]$ have to be encoded with $\log_2 n$ bits. \square

In the general case of SSLPs, the balancing in Reference [2, Theorem 3] was ensured using known algorithm [36], at the cost of increasing the SSLP size by $\log(n/m)$ and so the resulting data structure had size $O(m \cdot \log^\epsilon n \cdot \log(n/m))$.

Given a string $s \in \Sigma^*$, a rank query gets a position $1 \leq i \leq |s|$ and a symbol $a \in \Sigma$ and returns the number of a 's in the prefix of s of length i . A select query gets a symbol $a \in \Sigma$ and returns the position of the i th a in s (if it exists). Similarly to random access queries, the following result was shown [2, Theorem 2] assuming that the input SSLP is balanced, which we can ensure using Theorem 1.2.

COROLLARY 2.5. *Fix an arbitrary constant $\epsilon > 0$. From a given SSLP \mathcal{G} of size m such that the string $s = \llbracket \mathcal{G} \rrbracket$ has length n , one can construct in time $O(m \cdot |\Sigma| \cdot \log^\epsilon n)$ a data structure of size $O(m \cdot |\Sigma| \cdot \log^\epsilon n)$ that allows to answer rank and select queries in time $O(\log n / \log \log n)$.*

PROOF. Again, we follow the proof [2, Theorem 2] but first apply Theorem 1.2 to reduce the depth of the SSLP to $O(\log n)$. \square

For arbitrary grammars in Reference [2, Theorem 3] the balancing increased the SSLP size by a factor of $\log(n/m)$, and so the resulting data structure answering rank and select queries in time $O(\log n / \log \log n)$ had size $O(m \cdot |\Sigma| \cdot \log^\epsilon n \cdot \log(n/m))$.

Our balancing result also yields an improvement for the *compressed subsequence problem* [3]. Bille et al. [3] present an algorithm based on a *labelled successor* data structure. Given a string $s = a_1 \cdots a_n \in \Sigma^*$, a labelled successor query gets a position $1 \leq i \leq n$ and a symbol $a \in \Sigma$ and returns the minimal position $j > i$ with $a_j = a$ (or rejects if it does not exist). The following result is an improvement over [3], where the authors present two algorithms for the compressed subsequence problem: one with $O(m + m \cdot |\Sigma|/w)$ preprocessing time and $O(\log n \cdot \log w)$ query time, and another algorithm with $O(m + m \cdot |\Sigma| \cdot \log w/w)$ preprocessing time and $O(\log n)$ query time.

COROLLARY 2.6. *There is a data structure supporting labelled successor (and predecessor) queries on a string $s \in \Sigma^*$ of length n compressed by an SSLP of size m in the word RAM model with word size $w \geq \log_2 n$ using $O(m + m \cdot |\Sigma|/w)$ space, $O(m + m \cdot |\Sigma|/w)$ preprocessing time, and $O(\log n)$ query time.*

PROOF. In the preprocessing phase, we first reduce the depth of the given SSLP to $O(\log n)$ using Theorem 1.2. We compute for every variable X the length of $\llbracket X \rrbracket$ in time and space $O(m)$ as in the proof of Theorem 1.1. Additionally, for every variable X we compute a bitvector of length $|\Sigma|$ that encodes the set of symbols $a \in \Sigma$ that occur in $\llbracket X \rrbracket$. Notice that this information takes $O(m \cdot |\Sigma|)$ bits and fits into $O(m \cdot |\Sigma|/w)$ memory words. If $\rho(X) = YZ$, then the bitvector of X can be computed from the bitvectors of Y and Z by $O(|\Sigma|/w)$ many bitwise OR operations. Hence in total all bitvectors can be computed in time $O(m \cdot |\Sigma|/w)$.

A labelled successor query (for position i and symbol a) can now be answered in $O(\log n)$ time in a straightforward way: First, we compute the path $(X_0, X_1, \dots, X_\ell)$ in the derivation tree from the root X_0 to the symbol at the i th position. Then, we follow the path starting from the leaf upwards to find the maximal k such that $\rho(X_k) = X_{k+1}Y$ and $\llbracket Y \rrbracket$ contains the symbol a , or reject if no such

k exists. Finally, starting from Y , we navigate in time $O(\log n)$ to the leftmost leaf in the derivation tree that produces the symbol a . \square

A *minimal subsequence occurrence* of a string $p = a_1 a_2 \cdots a_k$ in a string $s = b_1 b_2 \cdots b_l$ is given by two positions i, j with $1 \leq i \leq j \leq l$ such that p is a subsequence of $b_i b_{i+1} \cdots b_j$ (i.e., $b_i b_{i+1} \cdots b_j$ belongs to the language $\Sigma^* a_1 \Sigma^* a_2 \cdots \Sigma^* a_k \Sigma^*$) but p is neither a subsequence of $b_{i+1} \cdots b_j$ nor of $b_i \cdots b_{j-1}$. Following the proof of Reference [3, Theorem 1], we obtain the following.

COROLLARY 2.7. *Given an SSLP \mathcal{G} of size m producing a string $s \in \Sigma^*$ of length n and a pattern $p \in \Sigma^*$ one can compute all minimal subsequence occurrences of p in s in space $O(m + m \cdot |\Sigma|/w)$ and time $O(m + m \cdot |\Sigma|/w + |p| \cdot \log n \cdot \text{occ})$ where $w \geq \log n$ is the word size and occ is the number of minimal subsequence occurrences of p in s .*

Corollary 2.7 improves Reference [3, Theorem 1], which states the existence of two algorithms for the computation of all minimal subsequence occurrences with the following running times (the space bounds are the same as in Corollary 2.7):

- $O(m + m \cdot |\Sigma|/w + |p| \cdot \log n \cdot \log w \cdot \text{occ})$,
- $O(m + m \cdot |\Sigma| \cdot \log w/w + |p| \cdot \log n \cdot \text{occ})$.

Let us briefly mention some other application of Theorem 1.2. As before let \mathcal{G} be an SSLP of size m for a string s of length n .

Computing Karp-Rabin fingerprints for compressed strings. This problem has been studied in Reference [6], where the reader can also find the definition of finger prints. Given two positions $i \leq j$ in s one wants to compute the Karp-Rabin fingerprint of the factor of s that starts at position i and ends at position j . In Reference [6] it was shown that one can compute from \mathcal{G} a data structure of size $O(m)$ that allows to compute fingerprints in time $O(\log n)$. First, the authors of Reference [6] present a very simple data structure of size $O(m)$ that allows to compute fingerprints in time $O(\text{depth}(\mathcal{G}))$. With Theorem 1.2, we can use this data structure to obtain a $O(\log n)$ -time solution. This simplifies the proof in Reference [6] considerably.

Computing runs, squares, and palindromes in SSLP-compressed strings. It is shown in Reference [23] that certain compact representations of the set of all runs, squares and palindromes in s (see Reference [23] for precise definitions) can be computed in time $O(m^3 \cdot \text{depth}(\mathcal{G}))$. With Theorem 1.2, we can improve the time bound to $O(m^3 \cdot \log n)$.

Real time traversal for SSLP-compressed strings. One wants to output the symbols of s from left to right and thereby spend constant time per symbol. A solution can be found in Reference [19]; a two-way version (where one can navigate in each step to the left or right neighboring position in s) can be found in Reference [33]. The drawback of these solutions is that they need workspace $O(\text{depth}(\mathcal{G}))$. With Theorem 1.2, we can reduce this to workspace $O(\log n)$.

Compressed range minimum queries. Range minimum data structure preprocesses a given string s of integers so that the following queries can be efficiently answered: Given $i \leq j$, what is the minimum element in s_i, \dots, s_j (the substring of s from position i to j). We are interested in the variant of the problem, in which the input is given as an SSLP \mathcal{G} . It is known, that after a preprocessing taking $O(|\mathcal{G}|)$ time, one can answer range minimum queries in time $O(\log n)$ [20, Theorem 1.1]. This implementation extends the data structure for random access for SSLP [8] with some additional information, which includes in particular adding standard range minimum data structures for subtrees leaving the heavy path and extending the original analysis. Using the balanced SSLP the same running time can be easily obtained, treating the balanced SSLP construction as a black-box, without the need of enhancing it. To this end, for each variable X we store the length ℓ_X of

the derived word $\llbracket X \rrbracket$ as well the minimum value in $\llbracket X \rrbracket$. In the following, let **range minimum queries (RMQ)**, $RMQ(X, i, j)$, be the range minimum query called on $\llbracket X \rrbracket$ for interval $[i, j]$. Given $RMQ(X, i, j)$, with the rule for X being $X \rightarrow YZ$ we proceed as follows:

- If the query asks about the minimum in the whole $\llbracket X \rrbracket$, i.e., $i = 1$ and $j = \ell_X$, then we return the minimum of $\llbracket X \rrbracket$; we call this case trivial in the following.
- If the whole range is within the substring generated by the first variable in the rule, i.e., $j \leq \ell_Y$, then we call $RMQ(Y, i, j)$.
- If the whole range is within the substring generated by the second nonterminal in a rule, i.e., $i > \ell_Y$, then we call $RMQ(Z, i - \ell_Y, j - \ell_Y)$.
- Otherwise, i.e., when $i \leq \ell_Y$ and $j > \ell_Y$ and $(i, j) \neq (1, \ell_X)$, the range spans over the substrings generated by both nonterminals. Thus, we compute the queries for two substrings and take their minimum, i.e., we return the minimum of $RMQ(Y, i, \ell_Y)$ and $RMQ(Z, 1, j - \ell_Y)$.

To see that the running time is $O(\text{depth}(\mathcal{G})) = O(\log n)$ observe first that the cost of trivial cases can be charged to the function that called them. Thus it is enough to estimate the number of nontrivial recursive calls. In the second and third case there is only one recursive call for a variable that is deeper in the derivation tree of the SSLP. In the fourth case there are two calls, but two nontrivial calls are made at most once during the whole computation: If two nontrivial calls are made in the fourth case, then one of them asks for the RMQ of a suffix of $\llbracket Y \rrbracket$ and the other call asks for the RMQ of a prefix of $\llbracket Z \rrbracket$. Moreover, every recursive call on a prefix of some string $\llbracket X' \rrbracket$ leads to at most one nontrivial call, which is again on a prefix of some string $\llbracket X'' \rrbracket$; and analogously for suffixes.

Lifshits' algorithm for compressed pattern matching [28]. The input consists of an SSLP \mathcal{P} for a pattern p and an SSLP \mathcal{T} for a text t and the question is whether p occurs in t . Lifshits' algorithm has a running time of $O(|\mathcal{P}| \cdot |\mathcal{T}|^2)$. It was conjectured by the author that the running time could be improved to $O(|\mathcal{P}| \cdot |\mathcal{T}| \cdot \log |t|)$. This follows easily from Theorem 1.2: The algorithm fills a table of size $|\mathcal{P}| \cdot |\mathcal{T}|$ and on each entry it calls a recursive subprocedure, whose running time is at most $\text{depth}(\mathcal{T})$. By Theorem 1.2, we can bound the running time by $O(\log |t|)$, which proves Lifshits' conjecture. Note, that in the meantime a faster algorithm with running time $O(|\mathcal{T}| \cdot \log |p|)$ [25] was found.

Smallest grammar problem. We conclude Part I of the article with a remark on the so-called *smallest grammar problem* for strings. In this problem one wants to compute for a given string w a smallest SSLP defining w . The decision variant of this problem is NP-hard, the best known approximation lower bound is $\frac{8569}{8568}$ [11], and the best known approximation algorithms have an approximation ratio of $O(\log(n/m_{\text{opt}}))$, where n is the length of the input string and m_{opt} the size of the smallest SSLP for the input string [11, 24, 26, 36]. Except for Reference [24], all these algorithms produce SSLPs of depth $O(\log n)$. It was discussed in Reference [24] that the reason for the lack of constant-factor approximation algorithms might be the fact that smallest SSLPs can have larger than logarithmic depth. Theorem 1.2 refutes this conjecture.

3 PART II: BALANCING CIRCUITS OVER ALGEBRAS

In this second part of the article, we prove our general balancing result Theorem 1.4.

Example of free monoids. For a gentle introduction into this more algebraic part of the article, let us illustrate the main ideas using the example of a free monoid $\mathcal{A} = \Sigma^*$, which is the underlying algebraic structure of SSLPs. Recall that in the proof of Theorem 1.2 we treated every symmetric centroid path X_0, X_1, \dots, X_p individually. Let L_1, \dots, L_s be the variables branching off the path to

the left and R_1, \dots, R_t be the variables branching off the path to the right. We were able to produce all suffixes of $L_1 \dots L_s$ and all prefixes of $R_1 \dots R_t$ in “small depth” by the suffix lemma on weighted strings (Proposition 2.2). Then every variable X_i can be written as a $u_i X_p v_i$ where u_i is a suffix of $L_1 \dots L_s$ and v_i is a prefix of $R_1 \dots R_t$.

A different approach would be to introduce special variables Z_i that produce strings with “holes” $u_i * v_i$, i.e., we replace in the above right-hand side $u_i X_p v_i$ the variable X_p (the last last variable on the symmetric centroid path) by the hole $*$. For the moment, we allow such variables Z_i , which will be eliminated in a second step. Observe that the variable Z_i is obtained from Z_{i+1} by inserting either $L_j *$ or $* R_j$ for some j into the hole $*$. In the end X_i is obtained from Z_i by inserting X_p , which closes the hole. Again, using the suffix lemma on weighted strings, we can balance the computation of the variables Z_i to achieve logarithmic depth of the SLP.

What we obtain in this way is not a string SLP anymore, but an SLP (or a circuit) over a two-sorted algebra $\hat{\mathcal{A}}$: Besides the sort of strings from Σ^* , it contains a second sort, namely so-called *contexts* (strings with holes), which can be formalized as functions $x \mapsto uxv$ on Σ^* . We write $\text{lin}(\Sigma^*)$ for the set of all such functions (the function $x \mapsto uxv$ is a linear function on Σ^*). The above variables Z_i would be of sort $\text{lin}(\Sigma^*)$; the hole $*$ in $u_i * v_i$ marks the position of the variable x .

Besides the usual concatenation on strings (which is an operation from $\Sigma^* \times \Sigma^*$ to Σ^*) the algebra $\hat{\mathcal{A}}$ contains an operation $\alpha : \Sigma^* \times \text{lin}(\Sigma^*) \rightarrow \Sigma^*$ to insert a string into a context (which corresponds to function application) and an operation $\gamma : \text{lin}(\Sigma^*) \times \text{lin}(\Sigma^*) \rightarrow \text{lin}(\Sigma^*)$ to insert a context into another context (which corresponds to the composition of functions). Finally, it has two operations that take a string w as input and return the context $w*$, respectively $*w$. An SLP over $\hat{\mathcal{A}}$ contains variables of two sorts, which either produce strings or contexts. Every variable is computed from other variables by applying the operations from the algebra $\hat{\mathcal{A}}$.

In a second step, the SLP over $\hat{\mathcal{A}}$ of logarithmic depth (whose construction we have sketched above) can be turned into an ordinary SSLP again. The reason is that every variable X that computes a context $u * v$ can be split into two component variables X_1 computing u and X_2 computing v . Furthermore, all operations on context variables can be simulated in an SSLP on these component variables. For example to translate the insertion of a context into another one, say $X = \alpha(Y, Z)$, we define $X_1 = Y_1 Z_1$ and $X_2 = Z_2 Y_2$.

At this point the reader might ask for the purpose of this detour via the two-sorted algebra $\hat{\mathcal{A}}$. Indeed, if we would only be interested in the free monoid $\mathcal{A} = \Sigma^*$ and SSLPs there would be no reason to do this detour. The main advantage of our detour is that it can be generalized to a large class of algebraic structures \mathcal{A} . It enables us to balance SLPs (or, equivalently, circuits) over \mathcal{A} using a general construction and thereby avoiding an adhoc approach for each individual structure \mathcal{A} . As for the case of the free monoid, our general construction proceeds in two steps.

- (1) First, we constructed from the input SLP over \mathcal{A} an equivalent logarithmic depth linear sized SLP over an extended algebra $\hat{\mathcal{A}}$. It turns out that this step can be carried out for every (multi-sorted) algebra \mathcal{A} . For this, we define $\hat{\mathcal{A}}$ as the extension of \mathcal{A} by so-called *unary linear term functions* (unary linear term function over the free monoid Σ^* are exactly functions of the form $x \mapsto uxv$).
- (2) In the second step, we have to transform the SLP over $\hat{\mathcal{A}}$ from the first step back into an SLP over \mathcal{A} . Thereby the size and depth of the SLP should only increase by a constant factor. This second step only works for algebras with a *finite subsumption base*. Roughly speaking, this means that all unary linear term functions over \mathcal{A} can be described by a finite number of parameterized term functions. In the example of the free monoid, this parameterized form is $x \mapsto y_1 x y_2$ where y_1, y_2 are the parameters that can be substituted by strings.

Outline. Part II of this article is structured as follows: In Sections 3.1.1–3.1.6 we start with definitions on (multi-sorted) algebras, terms, and straight-line programs over algebras. In Sections 3.1.7 and 3.2, we prove (a reformulation of) Theorem 1.4. Finally, in Section 3.3 and 3.4, we apply Theorem 1.4 to forest straight-line programs and top dags, which yields Theorem 1.3 from the introduction.

3.1 Algebras and Their Straight Line Programs

3.1.1 Ranked Trees. Let us fix a finite set \mathcal{S} of *sorts*. Later, we will assign to each sort $i \in \mathcal{S}$ a set A_i (of elements of sort i). Formally, an \mathcal{S} -sorted signature is a set of symbols Γ and a mapping $\text{type} : \Gamma \rightarrow \mathcal{S}^+$ that assigns to each symbol from Γ a non-empty word over the alphabet \mathcal{S} . For each $f \in \Gamma$ the number $|\text{type}(f)| - 1 \geq 0$ is also called the *rank* of f . Let $\Gamma_i \subseteq \Gamma$ ($i \geq 0$) be the set of all symbols in Γ of rank i .

In most cases, i.e., in proofs and definitions, the type mapping is either clear from the context or unimportant, therefore it is suppressed and the sorted signature (Γ, type) is simply denoted by Γ , which is called a sorted signature.

Let us also fix a second (infinite) \mathcal{S} -sorted signature \mathcal{X} , where every $x \in \mathcal{X}$ has rank zero; so formally: The sorted signature is $(\mathcal{X}, \text{type})$ and $\text{type}(x)$ is an element of \mathcal{S} for each $x \in \mathcal{X}$. Elements of \mathcal{X} are called *variables*. For $p \in \mathcal{S}$ let $\mathcal{X}_p = \{x \mid \text{type}(x) = p\}$. We assume that every set \mathcal{X}_p is infinite. We will always work with a finite subset \mathcal{Y} of \mathcal{X} . Take such a set \mathcal{Y} . For each sort $p \in \mathcal{S}$, we define the set of *terms* $\mathcal{T}_p(\Gamma, \mathcal{Y})$ of sort p by simultaneous induction as the smallest set such that the following holds:

- Every $x \in \mathcal{X}_p \cap \mathcal{Y}$ belongs to $\mathcal{T}_p(\Gamma, \mathcal{Y})$.
- If $f \in \Gamma_n$ with $\text{type}(f) = p_1 \cdots p_n q$ and $t_i \in \mathcal{T}_{p_i}(\Gamma, \mathcal{Y})$ for $1 \leq i \leq n$, then $f(t_1, t_2, \dots, t_n) \in \mathcal{T}_q(\Gamma, \mathcal{Y})$.

We write $\mathcal{T}_p(\Gamma)$ for $\mathcal{T}_p(\Gamma, \emptyset)$, and call its elements *ground terms* (of sort p). Note that if $a \in \Gamma_0$ and $\text{type}(a) = p \in \mathcal{S}$ then $a() \in \mathcal{T}_p(\Gamma)$. In this case, we write a for $a()$ and call a a constant of sort p . Let $\mathcal{T}(\Gamma, \mathcal{Y}) = \bigcup_{p \in \mathcal{S}} \mathcal{T}_p(\Gamma, \mathcal{Y})$.

Elements of $\mathcal{T}(\Gamma, \mathcal{Y})$ can be viewed as node labeled trees, where leaves are labeled with symbols from $\Gamma_0 \cup \mathcal{Y}$ and every internal node is labeled with a symbol from some Γ_n with $n \geq 1$: The root of the tree corresponding to the term $f(t_1, t_2, \dots, t_n)$ is labeled with f and its direct subtrees are the trees corresponding to t_1, \dots, t_n . Note that the composition of two functions $f : A \rightarrow B$ and $g : B \rightarrow C$ is denoted by $g \circ f$, in particular we first apply f followed by g .

For a term t , we define the size $|t|$ of t as the number of edges of the corresponding tree. Equivalently, $|t|$ is inductively defined as follows: If $t = x$ is a variable, then $|t| = 0$. If $t = f(t_1, t_2, \dots, t_n)$ for $f \in \Gamma$, then $|t| = n + \sum_{i=1}^n |t_i|$. The *depth* of a term t is denoted by $\text{depth}(t)$ and defined inductively as usual: If $t = x$ is a variable, then $\text{depth}(t) = 0$. If $t = f(t_1, t_2, \dots, t_n)$ for $f \in \Gamma$, then $\text{depth}(t) = \max\{1 + \text{depth}(t_i) \mid 1 \leq i \leq n\}$ with $\max \emptyset = 0$.

Definition 3.1 (Substitutions). A *substitution* is a mapping $\eta : \mathcal{Y} \rightarrow \mathcal{T}(\Gamma, \mathcal{Z})$ for finite (not necessarily disjoint) subsets $\mathcal{Y}, \mathcal{Z} \subseteq \mathcal{X}$ such that $y \in \mathcal{Y} \cap \mathcal{X}_p$ implies $\eta(y) \in \mathcal{T}_p(\Gamma, \mathcal{Z})$. If $\mathcal{Z} = \emptyset$, then we speak of a *ground substitution*. For $t \in \mathcal{T}(\Gamma, \mathcal{Y})$, we define the term $\eta(t)$ by replacing simultaneously all occurrences of variables in t by their images under η . Formally, we extend $\eta : \mathcal{Y} \rightarrow \mathcal{T}(\Gamma, \mathcal{Z})$ to a mapping $\eta : \mathcal{T}(\Gamma, \mathcal{Y}) \rightarrow \mathcal{T}(\Gamma, \mathcal{Z})$ by $\eta(f(t_1, \dots, t_n)) = f(\eta(t_1), \dots, \eta(t_n))$ (in particular, $\eta(a) = a$ for $a \in \Gamma_0$). A *variable renaming* is a bijective substitution $\eta : \mathcal{Y} \rightarrow \mathcal{Z}$ for finite variable sets \mathcal{Y} and \mathcal{Z} of the same size.

Definition 3.2 (Contexts). Let $p, q \in \mathcal{S}$. We define the set of *contexts* $\mathcal{C}_{pq}(\Gamma, \mathcal{Y})$ as the set of all terms $t \in \mathcal{T}_q(\Gamma, \mathcal{Y} \cup \{x\})$, where $x \in \mathcal{X}_p \setminus \mathcal{Y}$ is a fresh variable such that (i) $t \neq x$, (ii) and x

occurs exactly once in t . We call x the *main variable* of t and \mathcal{Y} the set of auxiliary variables of t .¹ We write $C_{pq}(\Gamma)$ for $C_{pq}(\Gamma, \emptyset)$. Elements of $C_{pq}(\Gamma)$ are called *ground contexts*. Let $C(\Gamma, \mathcal{Y}) = \bigcup_{p,q \in S} C_{pq}(\Gamma, \mathcal{Y})$ and $C(\Gamma) = C(\Gamma, \emptyset)$. For $s \in C_{qr}(\Gamma, \mathcal{Y})$ and $t \in \mathcal{T}_q(\Gamma, \mathcal{Z})$ (or $t \in C_{pq}(\Gamma, \mathcal{Z})$) we define $s[t] \in \mathcal{T}_r(\Gamma, \mathcal{Y} \cup \mathcal{Z})$ ($s[t] \in C_{pr}(\Gamma, \mathcal{Y} \cup \mathcal{Z})$) as the result of replacing the unique occurrence of the main variable in s by t . Formally, we can define $s[t]$ as $\eta(s)$ where η is the substitution with domain $\{x\}$ and $\eta(x) = t$, where x is the main variable of s . An *atomic context* is a context of the form $f(y_1, \dots, y_{k-1}, x, y_{k+1}, \dots, y_k)$ where x is the main variable and the y_i are the auxiliary variables (we can have $y_i = y_j$ for $i \neq j$). Note that there are only finitely many atomic contexts up to renaming of variables.

3.1.2 Algebras. We will produce strings, trees, and forests by ground terms (also called algebraic expressions in this context) over certain (multi-sorted) algebras. These expressions will be compressed by directed acyclic graphs. In this section, we introduce the generic framework, which will be instantiated several times later.

Fix a finite \mathcal{S} -sorted signature Γ . A Γ -*algebra* is a tuple $\mathcal{A} = ((A_p)_{p \in \mathcal{S}}, (f^{\mathcal{A}})_{f \in \Gamma})$ where every A_p is a non-empty set (the universe of sort p or the set of elements of sort p) and for every $f \in \Gamma_n$ with $\text{type}(f) = p_1 p_2 \dots p_n q$, $f^{\mathcal{A}} : \prod_{1 \leq j \leq n} A_{p_j} \rightarrow A_q$ is an n -ary function. We also say that Γ is the *signature* of \mathcal{A} . In our settings, the sets A_p will be always pairwise disjoint, but formally we do not need this. Quite often, we will identify the function $f^{\mathcal{A}}$ with the symbol f . Functions of arity zero are elements of some A_p . A ground term $t \in \mathcal{T}_p(\Gamma)$ can be viewed as an algebraic expression over \mathcal{A} that evaluates to an element $t^{\mathcal{A}} \in A_p$ in the natural way. For $x \in \bigcup_{p \in \mathcal{S}} A_p$, we also write $x \in \mathcal{A}$, and for A_p we also write \mathcal{A}_p .

When we define a Γ -algebra, we usually will not specify the types of the symbols in Γ . Instead, we just list the sets A_p ($p \in \mathcal{S}$) and the functions $f^{\mathcal{A}}$ ($f \in \Gamma$) including their domains. The latter implicitly determine the types of the symbols in Γ .

Example 3.3. A well known example of a multi-sorted algebra is a vector space. More precisely, it can be formalized as a Γ -algebra, where $\Gamma = \{\bar{0}, 0, 1, \oplus, \odot, +, \cdot\}$ is a \mathcal{S} -sorted signature for $\mathcal{S} = \{v, s\}$. Here, v stands for “vectors” and s stands for “scalars”. The types of the symbols in Γ are defined as follows:

- $\text{type}(\bar{0}) = v$ (the zero vector),
- $\text{type}(0) = s$ (the 0-element of the scalar field),
- $\text{type}(1) = s$ (the 1-element of the scalar field),
- $\text{type}(\oplus) = vv v$ (vector addition),
- $\text{type}(\odot) = sv v$ (multiplication of a scalar by a vector),
- $\text{type}(+) = sss$ (addition in the field of scalars),
- $\text{type}(\cdot) = sss$ (multiplication in the field of scalars).

Note that we cannot define non-trivial vectors by ground terms. For this, we should add some constants of type v to the signature. For the vector space F^n for a field F , we might for instance add the constants e_1, \dots, e_n , where e_i denotes the i th unit vector in the standard basis.

From the sets $\mathcal{T}_p(\Gamma)$ one can construct the *free term algebra*

$$\mathcal{T}(\Gamma) = ((\mathcal{T}_p(\Gamma))_{p \in \mathcal{S}}, (f)_{f \in \Gamma}),$$

where every ground term evaluates to itself. For every Γ -algebra \mathcal{A} , the mapping $t \mapsto t^{\mathcal{A}}$ ($t \in \mathcal{T}(\Gamma)$) is a homomorphism from the free term algebra to \mathcal{A} . We need the technical assumption

¹Since also \mathcal{Y} may contain a variable y that occurs exactly once in t , we explicitly have to declare a variable as the main variable. Most of the times, the main variable will be denoted with x .

that this homomorphism is surjective, i.e., for every $a \in \mathcal{A}$ there exists a ground term $t \in \mathcal{T}(\Gamma)$ with $a = t^{\mathcal{A}}$. In our concrete applications this assumption will be satisfied. Moreover, one can always replace \mathcal{A} by the subalgebra induced by the elements $t^{\mathcal{A}}$ (we will say more about this later).

For a Γ -algebra $\mathcal{A} = ((A_p)_{p \in S}, (f^{\mathcal{A}})_{f \in \Gamma})$, a variable $x \in \mathcal{X}_p$ and $a \in A_p$, we define the $(\Gamma \cup \{x\})$ -algebra $\mathcal{A}[x/a] = ((A_p)_{p \in S}, (f^{\mathcal{A}[x/a]})_{f \in \Gamma \cup \{x\}})$ by $f^{\mathcal{A}[x/a]} = f^{\mathcal{A}}$ for $f \in \Gamma$ and $x^{\mathcal{A}[x/a]} = a$.

Definition 3.4 (Unary Linear Term Functions). Given a Γ -algebra \mathcal{A} and a ground context $t \in C_{pq}(\Gamma)$ with main variable x , we define the function $t^{\mathcal{A}} : A_p \rightarrow A_q$ by $t^{\mathcal{A}}(a) = t^{\mathcal{A}[x/a]}$ for all $a \in A_p$. We call $t^{\mathcal{A}}$ a **unary linear term function (ULTF)**. We write $\text{lin}_{pq}(\mathcal{A})$ for the set of all ULTFs $t^{\mathcal{A}}$ with $t \in C_{pq}(\Gamma)$.

Example 3.5. Consider the the vector space \mathbb{R}^2 in the context of Example 3.3 and let

$$t = e_1 \oplus ((1 + 1) \odot (x_v \oplus e_2)) \in C_{vv}$$

(recall that v is the sort of vectors). The corresponding ULTF is the affine mapping $x \mapsto 2x \oplus (1, 2)^T$ on \mathbb{R}^2 ($(1, 2)^T$ is the column vector with entries 1 and 2).

As another example note that a ULTF, where the underlying algebra is a ring \mathcal{R} (this is a one-sorted algebra), is nothing else than a linear polynomial over \mathcal{R} in a single variable x .

3.1.3 Straight-line Programs. Let Γ be any \mathcal{S} -sorted signature. A *straight-line program* over Γ (Γ -SLP for short) is a tuple $\mathcal{G} = (\mathcal{V}, \rho, S)$, where $\mathcal{V} \subseteq \mathcal{X}$ is a finite set of variables, $S \in \mathcal{V}$ is the *start variable* and $\rho : \mathcal{V} \rightarrow \mathcal{T}(\Gamma, \mathcal{V})$ is a substitution (the so-called *right-hand side mapping*) such that the edge relation $E(\mathcal{G}) = \{(y, z) \in \mathcal{V} \times \mathcal{V} \mid z \text{ occurs in } \rho(y)\}$ is acyclic. This implies that there exists an $n \geq 1$ such that $\rho^n : \mathcal{T}(\Gamma, \mathcal{V}) \rightarrow \mathcal{T}(\Gamma)$ (the n -fold composition of ρ) is a ground substitution (we can choose $n = |\mathcal{V}|$). For this n , we write ρ^* for ρ^n . Note that $\rho^* \circ \rho = \rho \circ \rho^* = \rho^*$. The term defined by \mathcal{G} is $\llbracket \mathcal{G} \rrbracket := \rho^*(S)$; it is also called the *derivation tree* of \mathcal{G} .

In many papers on straight-line programs, the variables of a Γ -SLP are denoted by capital letters X, Y, Z, X' , and so on. We follow this tradition. For a variable $X \in \mathcal{V}$, we also write $\llbracket X \rrbracket_{\mathcal{G}}$ (or $\llbracket X \rrbracket$ if \mathcal{G} is clear from the context) for the ground term $\rho^*(X)$.

Let \mathcal{A} be a Γ -algebra. A Γ -SLP $\mathcal{G} = (\mathcal{V}, \rho, S)$ is also called an SLP over the algebra \mathcal{A} . We can evaluate every variable $X \in \mathcal{V}$ to its value $\rho^*(X)^{\mathcal{A}} = \llbracket X \rrbracket^{\mathcal{A}} \in \mathcal{A}$ in \mathcal{A} . It is important to distinguish this value from the syntactically computed ground term $\rho^*(X)$ (which is the evaluation of X in the free term algebra). Also note that in part I of the article, we used the notation $\llbracket X \rrbracket$ for variables of string straight-line programs, which are obtained from the above general definition by taking a free monoid Σ^* for the structure \mathcal{A} . In other words, a string $\llbracket X \rrbracket$ from the first part of the article would be denoted with $\llbracket X \rrbracket^{\Sigma^*}$ in the second part of the article. The reason for this change in notation is twofold. First, we did not want to overload the notation in Part I (especially for readers that are only interested in the balancing result for strings); hence, we decided to omit the superscripts Σ^* there. Second, in the following sections the ground terms $\llbracket X \rrbracket$ are the important objects, which justifies a short notation for them.

The term $\rho(X)$ is also called the *right-hand side* of the variable $X \in \mathcal{V}$. By adding fresh variables, we can transform every Γ -SLP in linear time into a so-called *standard Γ -SLP*, where all right-hand sides have the form $f(X_1, \dots, X_n)$ for variables X_1, \dots, X_n (we can have $X_i = X_j$ for $i \neq j$). A standard Γ -SLP \mathcal{G} is the same object as a DAG with Γ -labelled nodes: The DAG is $(\mathcal{V}, E(\mathcal{G}))$, and if $\rho(X) = f(X_1, \dots, X_n)$, then node X is labelled with f . Since the order of the edges (X, X_i) ($1 \leq i \leq n$) is important, and we may have $X_i = X_j$ for $i \neq j$ we formally replace the edge (X, X_i) by the triple (X, i, X_i) . A Γ -SLP interpreted over a Γ -algebra \mathcal{A} is also called an *algebraic circuit* over \mathcal{A} .

- For all $p, q \in \mathcal{S}$, we set $\text{type}(\alpha_{pq}) = p(p, q)q$.

Definition 3.8 ($\hat{\Gamma}$ -algebra $\hat{\mathcal{T}}(\Gamma)$). The $\hat{\Gamma}$ -algebra $\hat{\mathcal{T}}(\Gamma) = ((A_s)_{s \in \mathcal{S} \cup \mathcal{S}^2}, (f^{\hat{\mathcal{T}}(\Gamma)})_{f \in \hat{\Gamma}})$ is defined as follows: The sets A_p and A_{pq} for $p, q \in \mathcal{S}$ are defined as

- $A_p = \mathcal{T}_p(\Gamma)$ and
- $A_{pq} = C_{pq}(\Gamma)$.

The operations $g^{\hat{\mathcal{T}}(\Gamma)}$ ($g \in \hat{\Gamma}$) are defined as follows, where we write g instead of $g^{\hat{\mathcal{T}}(\Gamma)}$:

- For every symbol $f \in \Gamma_n$ the algebra $\hat{\mathcal{T}}(\Gamma)$ inherits the function $f^{\mathcal{T}(\Gamma)}$ from $\mathcal{T}(\Gamma)$.
- For every symbol $f \in \Gamma_n$ with $\text{type}(f) = p_1 \cdots p_n q$ ($n \geq 1$) and every $1 \leq k \leq n$, we define the $(n-1)$ -ary operation

$$\hat{f}_k : \prod_{\substack{1 \leq i \leq n \\ i \neq k}} \mathcal{T}_{p_i}(\Gamma) \rightarrow C_{p_k q}(\Gamma)$$

by $\hat{f}_k(t_1, \dots, t_{k-1}, t_{k+1}, \dots, t_n) = f(t_1, \dots, t_{k-1}, x, t_{k+1}, \dots, t_n)$ for all $t_i \in \mathcal{T}_{p_i}(\Gamma)$ ($1 \leq i \leq n$, $i \neq k$).

- For all $p, q, r \in \mathcal{S}$ the binary operation $\gamma_{pqr} : C_{pq}(\Gamma) \times C_{qr}(\Gamma) \rightarrow C_{pr}(\Gamma)$ is defined by $\gamma_{pqr}(t, s) = s[t]$.
- For all $p, q \in \mathcal{S}$ the binary operation $\alpha_{pq} : \mathcal{T}_p(\Gamma) \times C_{pq}(\Gamma) \rightarrow \mathcal{T}_q(\Gamma)$ is defined by $\alpha_{pq}(t, s) = s[t]$.

The definition of the operations α_{pq} and γ_{pqr} suggests to write $s[t]$ instead of $\alpha_{pq}(t, s)$ or $\gamma_{pqr}(t, s)$, which we will do most of the times. Recall the definition of ULTFs from Definition 3.4. An *atomic ULTF* is of the form $z \mapsto f^{\mathcal{A}}(a_1, \dots, a_{k-1}, z, a_{k+1}, \dots, a_n)$ for $f \in \Gamma_n$ with $\text{type}(f) = p_1 \cdots p_n q$ and $a_i \in A_{p_i}$ for $(1 \leq i \leq n, i \neq k)$. We denote this function with $f^{\mathcal{A}}(a_1, \dots, a_{k-1}, \cdot, a_{k+1}, \dots, a_n)$ in the following. At this point, we use the assumption that every element of \mathcal{A} can be written as $t^{\mathcal{A}}$ for a ground term t . Hence, the elements a_i are defined by terms, which ensures that $f^{\mathcal{A}}(a_1, \dots, a_{k-1}, \cdot, a_{k+1}, \dots, a_n)$ is indeed a ULTF. It is easy to see that every ULTF is the composition of finitely many atomic ULTFs.

Definition 3.9 ($\hat{\Gamma}$ -algebra $\hat{\mathcal{A}}$). Given a Γ -algebra $\mathcal{A} = ((A_p)_{p \in \mathcal{S}}, (f^{\mathcal{A}})_{f \in \Gamma})$ we define the $\hat{\Gamma}$ -algebra $\hat{\mathcal{A}} = ((B_s)_{s \in \mathcal{S} \cup \mathcal{S}^2}, (f^{\hat{\mathcal{A}}})_{f \in \hat{\Gamma}})$ as follows: The sets B_p and B_{pq} for $p, q \in \mathcal{S}$ are defined as

- $B_p = A_p$ and
- $B_{pq} = \text{lin}_{pq}(\mathcal{A})$.

The operations $g^{\hat{\mathcal{A}}}$ ($g \in \hat{\Gamma}$) are defined as follows, where we write g instead of $g^{\hat{\mathcal{A}}}$.

- Every $f \in \Gamma$ is interpreted as $f^{\hat{\mathcal{A}}} = f^{\mathcal{A}}$.
- For every symbol $f \in \Gamma_n$ with $\text{type}(f) = p_1 \cdots p_n q$ ($n \geq 1$) and every $1 \leq k \leq n$, we define the $(n-1)$ -ary operation

$$\hat{f}_k : \prod_{\substack{1 \leq i \leq n \\ i \neq k}} A_{p_i} \rightarrow \text{lin}_{p_k q}(\mathcal{A})$$

by $\hat{f}_k(a_1, \dots, a_{k-1}, a_{k+1}, \dots, a_n) = f^{\mathcal{A}}(a_1, \dots, a_{k-1}, \cdot, a_{k+1}, \dots, a_n)$ for all $a_i \in A_{p_i}$ ($1 \leq i \leq n$, $i \neq k$).

- For all $p, q, r \in \mathcal{S}$ the binary operation $\gamma_{pqr} : \text{lin}_{pq}(\mathcal{A}) \times \text{lin}_{qr}(\mathcal{A}) \rightarrow \text{lin}_{pr}(\mathcal{A})$ is defined as function composition: $\gamma_{pqr}(g, h) = h \circ g$.

- For all $p, q \in \mathcal{S}$ the binary operation $\alpha_{pq} : A_p \times \text{lin}_{pq}(\mathcal{A}) \rightarrow A_q$ is defined as function application: $\alpha_{pq}(a, g) = g(a)$.

Note that Definitions 3.8 and 3.9 are consistent in the following sense: If we apply the construction from Definition 3.9 for $\mathcal{A} = \mathcal{T}(\Gamma)$ (the free term algebra), then we obtain an isomorphic copy of the algebra $\hat{\mathcal{T}}(\Gamma)$ from Definition 3.8, i.e., $\widehat{\mathcal{T}(\Gamma)} \cong \hat{\mathcal{T}}(\Gamma)$. Moreover, the mappings $t \mapsto t^{\mathcal{A}}$ (for ground terms t) and $c \mapsto c^{\mathcal{A}}$ (for ground contexts c) yield a canonical surjective morphism from $\hat{\mathcal{T}}(\Gamma)$ to $\hat{\mathcal{A}}$ that extends the canonical morphism from the free term algebra $\mathcal{T}(\Gamma)$ to \mathcal{A} .

Example 3.10. If $\mathcal{A} = (\Sigma^*, \cdot)$ is the free monoid over the finite alphabet Σ (i.e., \cdot is the concatenation function: $u \cdot v = uv$), then $\hat{\mathcal{A}}$ is the extended algebra explained in the example at the beginning of Section 3: The unary function $\hat{\cdot}_1$ (respectively, $\hat{\cdot}_2$) turns a string $w \in \Sigma^*$ into the unary function $x \mapsto xw$ (respectively, $x \mapsto wx$). The function γ inserts into a unary function another unary function, and α inserts into a unary function a string.

3.1.5 Tree Straight-line Programs. Recall the definition of the $\mathcal{S} \cup \mathcal{S}^2$ -sorted signature $\hat{\Gamma}$ in Equation (7). A $\hat{\Gamma}$ -SLP \mathcal{G} that evaluates in the $\hat{\Gamma}$ -algebra $\hat{\mathcal{T}}(\Gamma)$ to a ground term (i.e., $\llbracket \mathcal{G} \rrbracket^{\hat{\mathcal{T}}(\Gamma)} \in \mathcal{T}(\Gamma)$) is also called a **tree straight-line program over Γ (Γ -TSLP)** [15, 17, 31]. Recall that $\hat{\Gamma}$ contains for every $f \in \Gamma_n$ with $n \geq 1$ the unary symbols \hat{f}_k ($1 \leq k \leq n$). Right-hand sides of the form $\hat{f}_k(X_1, \dots, X_{k-1}, X_{k+1}, \dots, X_n)$ in a Γ -TSLP are written for better readability as $f(X_1, \dots, X_{k-1}, x, X_{k+1}, \dots, X_n)$. This is also the notation used in References [15, 17, 31]. For right-hand sides of the form $\alpha_{pq}(X, Y)$ or $\gamma_{pqr}(X, Y)$, we write $X[Y]$.

Example 3.11. Let us assume that \mathcal{S} consists of a single sort. Consider the Γ -TSLP

$$\mathcal{G} = (\{S, X_1, \dots, X_7\}, \rho, S)$$

with $\Gamma_2 = \{f, g\}$, $\Gamma_0 = \{a, b\}$ and $\rho(S) = X_1[X_2]$, $\rho(X_1) = X_3[X_3]$, $\rho(X_2) = X_4[X_5]$, $\rho(X_3) = f(x, X_7)$, $\rho(X_4) = X_6[X_6]$, $\rho(X_5) = a$, $\rho(X_6) = g(X_7, x)$, $\rho(X_7) = b$. We get

- $\llbracket X_6 \rrbracket^{\hat{\mathcal{T}}(\Gamma)} = \rho^*(X_6)^{\hat{\mathcal{T}}(\Gamma)} = g(b, x)$,
- $\llbracket X_4 \rrbracket^{\hat{\mathcal{T}}(\Gamma)} = \rho^*(X_4)^{\hat{\mathcal{T}}(\Gamma)} = g(b, x)[g(b, x)] = g(b, g(b, x))$,
- $\llbracket X_3 \rrbracket^{\hat{\mathcal{T}}(\Gamma)} = \rho^*(X_3)^{\hat{\mathcal{T}}(\Gamma)} = f(x, b)$,
- $\llbracket X_2 \rrbracket^{\hat{\mathcal{T}}(\Gamma)} = \rho^*(X_2)^{\hat{\mathcal{T}}(\Gamma)} = g(b, g(b, x))[a] = g(b, g(b, a))$,
- $\llbracket X_1 \rrbracket^{\hat{\mathcal{T}}(\Gamma)} = \rho^*(X_1)^{\hat{\mathcal{T}}(\Gamma)} = f(x, b)[f(x, b)] = f(f(x, b), b)$, and
- $\llbracket \mathcal{G} \rrbracket^{\hat{\mathcal{T}}(\Gamma)} = \rho^*(S)^{\hat{\mathcal{T}}(\Gamma)} = f(f(x, b), b)[g(b, g(b, a))] = f(f(g(b, g(b, a)), b), b)$.

3.1.6 From TSLPs to SLPs. Fix a Γ -algebra \mathcal{A} . Our first goal is to transform a Γ -TSLP \mathcal{G} into a Γ -SLP \mathcal{H} of size $O(|\mathcal{G}|)$ and depth $O(\text{depth}(\mathcal{G}))$ such that $\llbracket \mathcal{H} \rrbracket^{\mathcal{A}} = \llbracket \mathcal{G} \rrbracket^{\mathcal{A}}$. For this, we have to restrict the class of Γ -algebras. For instance, for the free term algebra the above transformation cannot be achieved in general: The chain tree $t_n = f(f(f(\dots f(a) \dots))$ with 2^n occurrences of f can be easily produced by a $\{a, f\}$ -TSLP of size $O(n)$ but the only DAG (= SLP over the free term algebra $\mathcal{T}(\{a, f\})$) for t_n is t_n itself. We restrict ourselves to algebras with a finite subsumption base, as defined below. Such algebras have been implicitly used in our recent papers [15, 17].

Definition 3.12 (Equivalence and Subsumption Preorder in \mathcal{A}). For contexts $s, t \in C_{pq}(\Gamma, \mathcal{Y})$, we say that s and t are *equivalent* in \mathcal{A} if for every ground substitution $\eta : \mathcal{Y} \rightarrow \mathcal{T}(\Gamma)$ we have $\eta(s)^{\mathcal{A}} = \eta(t)^{\mathcal{A}}$ (which is an ULTF).

For contexts $s \in C_{pq}(\Gamma, \mathcal{Y})$ and $t \in C_{pq}(\Gamma, \mathcal{Z})$, we say that t *subsumes* s in \mathcal{A} or that s is *subsumed* by t in \mathcal{A} ($t \leq^{\mathcal{A}} s$ for short) if there exists a substitution $\zeta : \mathcal{Z} \rightarrow \mathcal{T}(\Gamma, \mathcal{Y})$ such that s and $\zeta(t)$ are equivalent in \mathcal{A} .

A *subsumption base* of \mathcal{A} is a set of (not necessarily ground) contexts C such that for every context s there exists a context $t \in C$ with $t \leq^{\mathcal{A}} s$.

It is easy to see that $\leq^{\mathcal{A}}$ is reflexive and transitive but in general not antisymmetric. Moreover, the relation $\leq^{\mathcal{A}}$ satisfies the following monotonicity property:

LEMMA 3.13. *Let $s \in C_{qr}(\Gamma, \mathcal{Y})$, $t_1 \in C_{pq}(\Gamma, \mathcal{Z}_1)$ and $t_2 \in C_{pq}(\Gamma, \mathcal{Z}_2)$ be contexts such that $\mathcal{Y} \cap \mathcal{Z}_1 = \emptyset$ and $\mathcal{Y} \cup \mathcal{Z}_1 \cup \mathcal{Z}_2$ contains none of the main variables of s, t_1, t_2 . If $t_1 \leq^{\mathcal{A}} t_2$, then $s[t_1] \leq^{\mathcal{A}} s[t_2]$.*

PROOF. Since t_1 subsumes t_2 in \mathcal{A} there exists a substitution $\zeta : \mathcal{Z}_1 \rightarrow \mathcal{T}(\Gamma, \mathcal{Z}_2)$ such that for every ground substitution $\eta : \mathcal{Z}_2 \rightarrow \mathcal{T}(\Gamma)$ we have

$$\eta(t_2)^{\mathcal{A}} = \eta(\zeta(t_1))^{\mathcal{A}}.$$

Define the substitution $\zeta' : \mathcal{Y} \cup \mathcal{Z}_1 \rightarrow \mathcal{T}(\Gamma, \mathcal{Y} \cup \mathcal{Z}_2)$ by

$$\zeta'(y) = \begin{cases} \zeta(y) & \text{if } y \in \mathcal{Z}_1, \\ y & \text{if } y \in \mathcal{Y}. \end{cases}$$

As $\mathcal{Z}_1 \cap \mathcal{Y} = \emptyset$ by the assumption, ζ' is well defined. It satisfies $\zeta'(t_1) = \zeta(t_1)$ and $\zeta'(s) = s$. For any ground substitution $\eta : \mathcal{Y} \cup \mathcal{Z}_2 \rightarrow \mathcal{T}(\Gamma)$, we have the following:

$$\begin{aligned} \eta(s[t_2])^{\mathcal{A}} &= (\eta(s)[\eta(t_2)])^{\mathcal{A}} \\ &= \eta(s)^{\mathcal{A}} \circ \eta(t_2)^{\mathcal{A}} \\ &= \eta(s)^{\mathcal{A}} \circ \eta(\zeta(t_1))^{\mathcal{A}} \\ &= \eta(\zeta'(s))^{\mathcal{A}} \circ \eta(\zeta'(t_1))^{\mathcal{A}} \\ &= (\eta(\zeta'(s))[\eta(\zeta'(t_1))])^{\mathcal{A}} \\ &= \eta(\zeta'(s[t_1]))^{\mathcal{A}}. \end{aligned}$$

This implies $s[t_1] \leq^{\mathcal{A}} s[t_2]$. □

We will be interested in algebras that have a finite subsumption base. To show that a set C is a finite subsumption base we will use the following lemma.

LEMMA 3.14. *Let \mathcal{A} be a Γ -algebra and let C be a finite set of contexts with the following properties:*

- *For every atomic context s there exists $t \in C$ with $t \leq^{\mathcal{A}} s$.*
- *For every atomic context s and every $t \in C$ such that $s[t]$ is defined and s and t do not share auxiliary variables, there exists $t' \in C$ with $t' \leq^{\mathcal{A}} s[t]$.*

Then C is a subsumption base.

PROOF. Assume that the two conditions from the lemma hold. We show by induction on s that for every context s there exists a context $t \in C$ with $t \leq^{\mathcal{A}} s$.

If $s = f(s_1, \dots, s_{i-1}, x, s_{i+1}, \dots, s_n)$ for some terms $s_1, \dots, s_{i-1}, s_{i+1}, \dots, s_n$, then s is subsumed in \mathcal{A} by the atomic context $f(y_1, \dots, y_{i-1}, x, y_{i+1}, \dots, y_n)$, which in turn is subsumed in \mathcal{A} by some $t \in C$. If $s = f(s_1, \dots, s_{i-1}, s', s_{i+1}, \dots, s_n)$ for some terms s_1, \dots, s_n and some context s' , then $f(y_1, \dots, y_{i-1}, s', y_{i+1}, \dots, y_n) \leq^{\mathcal{A}} s$ for fresh auxiliary variables $y_1, \dots, y_{i-1}, y_{i+1}, \dots, y_n$ (that neither occur in s' nor any context from C). By induction there exists $t' \in C$ with $t' \leq^{\mathcal{A}} s'$. By Lemma 3.13, we have $f(y_1, \dots, y_{i-1}, t', y_{i+1}, \dots, y_n) \leq^{\mathcal{A}} f(y_1, \dots, y_{i-1}, s', y_{i+1}, \dots, y_n)$. By the second assumption from the lemma, we have that $t'' \leq^{\mathcal{A}} f(y_1, \dots, y_{i-1}, t', y_{i+1}, \dots, y_n)$ for some $t'' \in C$. We get $t'' \leq^{\mathcal{A}} s$ by transitivity of $\leq^{\mathcal{A}}$. □

Remark 3.15. Recall that we made the technical assumption that every element a of \mathcal{A} can be written as $t^{\mathcal{A}}$ for a ground term \mathcal{A} . Let \mathcal{B} be the subalgebra of \mathcal{A} that is induced by all elements $t^{\mathcal{A}}$ for $t \in \mathcal{T}(\mathcal{A})$. It is obvious that every subsumption base of \mathcal{A} is also a subsumption base of \mathcal{B} .

Example 3.16. Every semiring $\mathcal{A} = (A, +, \times, a_1, \dots, a_n)$, where $a_1, \dots, a_n \in A$ are arbitrary constants, has a finite subsumption base. Here, we do not assume that \times is commutative, nor do we assume that identity elements with respect to $+$ or \times exist. In other words: $(A, +)$ is a commutative semigroup, (A, \times) is a semigroup and the left and right distributive law holds. The finite subsumption base $C(\mathcal{A})$ consists of the following contexts $axb + c$, $ax + c$, $xb + c$, $x + c$, axb , ax , xb , and x , where x is the main variable and a, b, c are auxiliary variables. We write ab instead of $a \times b$ and omit in axb brackets that are not needed due to the associativity of multiplication. To see that every context s is subsumed in \mathcal{A} by one of the contexts from $C(\mathcal{A})$, observe that a context defines a linear polynomial in the main variable x . Hence, every context is equivalent in \mathcal{A} to a context of the form $sxt + u$, $sx + u$, $xt + u$, $x + u$, sxt , sx , xt or x , where s, t, u are terms that contain the auxiliary parameters. Each of these contexts is subsumed by a context from $C(\mathcal{A})$ by the substitution ζ with $\zeta(a) = s$, $\zeta(b) = t$, and $\zeta(c) = u$.

Let us remark that the above proof can be adapted to the situation that also $+$ is not commutative. In that case, we have include the terms $c' + axb + c$, $c' + ax + c$, $c' + xb + c$, $c' + x + c$, $c' + axb$, $c' + ax$, $c' + xb$ and $c' + x$ to the set $C(\mathcal{A})$.

However, if $(A, +)$ has a neutral element, called 0 in the following, then $axb + c$, $ax + c$, $xb + c$, $x + c$ is a subsumption base. To see this observe that, for instance, axb is subsumed by $axb + c$, which is shown by the substitution $c \mapsto 0$.

Example 3.17. If Γ contains a symbol of rank at least one, then the free term algebra $\mathcal{T}(\Gamma)$ has no finite subsumption base: If C were a finite subsumption base of $\mathcal{T}(\Gamma)$, then every ground context could be obtained from some $t \in C$ by replacing the auxiliary parameters in t by ground terms. But this replacement does not change the length of the path from the root of the context to its main variable. Hence, we would obtain a bound for the length of the path from the root to the main variable in a ground context, which clearly does not exist.

LEMMA 3.18. *Assume that the Γ -algebra \mathcal{A} has a finite subsumption base. Then from a given Γ -TSLP \mathcal{G} one can compute in time $O(|\mathcal{G}|)$ a Γ -SLP \mathcal{H} of size $O(|\mathcal{G}|)$ and depth $O(\text{depth}(\mathcal{G}))$ such that $\llbracket \mathcal{G} \rrbracket^{\mathcal{A}} = \llbracket \mathcal{H} \rrbracket^{\mathcal{A}}$.*

PROOF. Let $C(\mathcal{A})$ be a finite subsumption base for \mathcal{A} . We say that a context $s \in C(\Gamma, \mathcal{Y})$ belongs to $C(\mathcal{A})$ up to variable renaming if there is a variable renaming $\theta : \mathcal{Y} \rightarrow \mathcal{Z}$ such that $\theta(s) \in C(\Gamma)$. Since the algebra \mathcal{A} is fixed, the set $C(\mathcal{A})$ has size $O(1)$. Assume that s and t are contexts with the following properties: (i) $s[t]$ is defined, (ii) s and t have no common auxiliary variable, and (iii) s and t belong to $C(\mathcal{A})$ up to variable renaming. We denote with $s \cdot t$ a context from $C(\mathcal{A})$ with $s \cdot t \leq^{\mathcal{A}} s[t]$. Since s and t have size $O(1)$ ($C(\mathcal{A})$ is a fixed set of contexts), we can compute from s, t in constant time the context $s \cdot t$ and a substitution ζ such that $s[t]$ and $\zeta(s \cdot t)$ are equivalent in \mathcal{A} . Similarly, one can compute from a given atomic context s in constant time a context $t \in C(\mathcal{A})$ and a ground substitution ζ such that s and $\zeta(t)$ are equivalent in \mathcal{A} .

Let $\mathcal{G} = (\mathcal{V}, \rho, S)$. We define $\mathcal{V}_0 = \{X \in \mathcal{V} \mid \rho^*(X)^{\hat{\tau}(\Gamma)} \in \mathcal{T}(\Gamma)\}$ and $\mathcal{V}_1 = \{X \in \mathcal{V} \mid \rho^*(X)^{\hat{\tau}(\Gamma)} \in C(\Gamma)\} = \mathcal{V} \setminus \mathcal{V}_0$. The Γ -SLP \mathcal{H} to be constructed will be denoted with $\mathcal{H} = (\mathcal{V}', \tau, S)$. We will have $\mathcal{V}_0 \subseteq \mathcal{V}'$. A variable $X \in \mathcal{V}_1$ is replaced in \mathcal{H} by a finite set \mathcal{Y}_X of variables. Moreover, we will compute a context $t_X \in C(\Gamma, \mathcal{Y}_X)$ that belongs to $C(\mathcal{A})$ up to variable renaming. We can assume that $\mathcal{Y}_X \cap \mathcal{Y}_{X'} = \emptyset = \mathcal{Y}_X \cap \mathcal{V}_0$ for all $X, X' \in \mathcal{V}_1$ with $X \neq X'$. The set of variables of \mathcal{H} is then $\mathcal{V}' = \mathcal{V}_0 \cup \bigcup_{X \in \mathcal{V}_1} \mathcal{Y}_X$. Moreover, \mathcal{H} will satisfy the following conditions:

- (a) If $X \in \mathcal{V}_0$, then $\rho^*(X)^{\hat{\mathcal{A}}} = \tau^*(X)^{\mathcal{A}}$ (which is an element of \mathcal{A}).
- (b) If $X \in \mathcal{V}_1$, then $\rho^*(X)^{\hat{\mathcal{A}}} = \tau^*(t_X)^{\mathcal{A}}$ (which is a ULTF on \mathcal{A}).

We construct \mathcal{H} bottom-up. That means that we process all variables in \mathcal{V} in a single pass over \mathcal{G} . When we process a variable $X \in \mathcal{V}$, we have already processed all variables X' that appear in $\rho(X)$. In particular, the set $\mathcal{Y}_{X'}$ and the context $t_{X'} \in C(\Gamma, \mathcal{Y}_{X'})$ (in case $X' \in \mathcal{V}_1$) are defined. In addition, X' satisfies the above conditions (a) and (b).

We proceed by a case distinction according to the right-hand side $\rho(X)$ of $X \in \mathcal{V}$. This right-hand side has one of the following four forms:

Case 1. $X \in \mathcal{V}_0$ and $\rho(X) = f(X_1, \dots, X_n)$ for $f \in \Gamma_n$ ($n \geq 0$) and $X_1, \dots, X_n \in \mathcal{V}_0$. Then, we set $\tau(X) = \rho(X)$. Clearly, the above condition (a) holds.

Case 2. $X \in \mathcal{V}_0$ and $\rho(X) = X'[X'']$ with $X' \in \mathcal{V}_1$, $X'' \in \mathcal{V}_0$. By induction, we have $\rho^*(X'')^{\hat{\mathcal{A}}} = \tau^*(X'')^{\mathcal{A}}$. Moreover, we have computed a context $t_{X'} \in C(\Gamma, \mathcal{Y}_{X'})$ that belongs to $C(\mathcal{A})$ up to variable renaming and such that $\rho^*(X')^{\hat{\mathcal{A}}} = \tau^*(t_{X'})^{\mathcal{A}}$. We define $\tau(X) = t_{X'}[X''] \in \mathcal{T}(\Gamma, \mathcal{Y}_{X'} \cup \{X''\})$ (that is, we replace the main variable in $t_{X'}$ by X'') and get

$$\begin{aligned} \rho^*(X)^{\hat{\mathcal{A}}} &= \rho^*(X')^{\hat{\mathcal{A}}}(\rho^*(X'')^{\hat{\mathcal{A}}}) = \tau^*(t_{X'})^{\mathcal{A}}(\tau^*(X'')^{\mathcal{A}}) \\ &= \tau^*(t_{X'}[X''])^{\mathcal{A}} = \tau^*(\tau(X))^{\mathcal{A}} = \tau^*(X)^{\mathcal{A}}. \end{aligned}$$

Case 3. $X \in \mathcal{V}_1$ and $\rho(X) = f(X_1, \dots, X_{k-1}, x, X_{k+1}, \dots, X_n)$ for $f \in \Gamma_n$ ($n \geq 1$) and $X_1, \dots, X_{k-1}, X_{k+1}, \dots, X_n \in \mathcal{V}_0$. By induction, we have $\rho^*(X_i)^{\hat{\mathcal{A}}} = \tau^*(X_i)^{\mathcal{A}}$ for $1 \leq i \leq n$, $i \neq k$. We can view $\rho(X)$ as an atomic context with main variable x and auxiliary variables $X_1, \dots, X_{k-1}, X_{k+1}, \dots, X_n$. Hence, we can compute $t_X \in C(\mathcal{A})$ with $t_X \leq^{\mathcal{A}} \rho(X)$. We rename the auxiliary variables of t_X such that they do not already belong to \mathcal{H} . Let \mathcal{Y}_X be the set of auxiliary variables of t_X . We then add all variables in \mathcal{Y}_X to \mathcal{H} . By the definition of $\leq^{\mathcal{A}}$ there is a substitution $\zeta : \mathcal{Y}_X \rightarrow \mathcal{T}(\Gamma, \{X_1, \dots, X_{k-1}, X_{k+1}, \dots, X_n\})$ such that

$$\rho^*(X)^{\hat{\mathcal{A}}} = \rho^*(\rho(X))^{\hat{\mathcal{A}}} = \tau^*(\rho(X))^{\mathcal{A}} = \tau^*(\zeta(t_X))^{\mathcal{A}}.$$

We define the right-hand side for every new variable $Y \in \mathcal{Y}_X$ by $\tau(Y) = \zeta(Y)$ and get $\rho^*(X)^{\hat{\mathcal{A}}} = \tau^*(\zeta(t_X))^{\mathcal{A}} = \tau^*(\tau(t_X))^{\mathcal{A}} = \tau^*(t_X)^{\mathcal{A}}$, which is point (b).

Case 4. $X \in \mathcal{V}_1$ with $\rho_{\mathcal{G}}(X) = X'[X'']$ and $X', X'' \in \mathcal{V}_1$. We have already defined the terms $t_{X'}, t_{X''}$ that belong to $C(\mathcal{A})$ up to variable renaming. The set of auxiliary variables of $t_{X'}$ (respectively, $t_{X''}$) is $\mathcal{Y}_{X'}$ (respectively, $\mathcal{Y}_{X''}$), and we have $\mathcal{Y}_{X'} \cap \mathcal{Y}_{X''} = \emptyset$. Moreover, by the induction hypothesis for X' and X'' we have $\rho^*(X')^{\hat{\mathcal{A}}} = \tau^*(t_{X'})^{\mathcal{A}}$ and $\rho^*(X'')^{\hat{\mathcal{A}}} = \tau^*(t_{X''})^{\mathcal{A}}$. We set $t_X := t_{X'} \cdot t_{X''} \in C(\mathcal{A})$. We rename the auxiliary variables of t_X such that they do not already belong to \mathcal{H} . Let \mathcal{Y}_X be the set of auxiliary variables of t_X . We then add every $Y \in \mathcal{Y}_X$ to \mathcal{H} . By definition of t_X , we have $t_X \leq^{\mathcal{A}} t_{X'}[t_{X''}]$, which implies that there is a substitution $\zeta : \mathcal{Y}_X \rightarrow \mathcal{T}(\Gamma, \mathcal{Y}_{X'} \cup \mathcal{Y}_{X''})$ with

$$\begin{aligned} \rho^*(X)^{\hat{\mathcal{A}}} &= \rho^*(X')^{\hat{\mathcal{A}}} \circ \rho^*(X'')^{\hat{\mathcal{A}}} = \tau^*(t_{X'})^{\mathcal{A}} \circ \tau^*(t_{X''})^{\mathcal{A}} \\ &= \tau^*(t_{X'}[t_{X''}])^{\mathcal{A}} = \tau^*(\zeta(t_X))^{\mathcal{A}}. \end{aligned}$$

We define the right-hand side for every new variable $Y \in \mathcal{Y}_X$ by $\tau(Y) = \zeta(Y)$ and get $\rho^*(X)^{\hat{\mathcal{A}}} = \tau^*(\zeta(t_X))^{\mathcal{A}} = \tau^*(\tau(t_X))^{\mathcal{A}} = \tau^*(t_X)^{\mathcal{A}}$, which is point (b).

The running time for the construction of \mathcal{H} is $O(|\mathcal{G}|)$, since for each variable $X \in \mathcal{V}$ we only spend constant time (see the remark from the first paragraph of the proof). In each step, we have to take a constant number of fresh auxiliary variables. We can take them from a list Y_1, Y_1, Y_3, \dots and store a pointer to the next free variable. \square

It is known [15, 17] that a ranked tree t of size n can be transformed in linear time into a tree straight-line program of size $O(n/\log_\sigma n)$ and depth $O(\log n)$, where σ is the number of different node labels that appear in t . With Lemma 3.18 it follows that for every algebra \mathcal{A} having a finite subsumption base one can compute in linear time from a given expression tree of size n an equivalent circuit of size $O(n/\log_\sigma n)$ and depth $O(\log n)$ (σ is a constant here, namely the number of operations of the algebra \mathcal{A}).

3.1.7 Main Result for Γ -straight Line Programs. We now state the main technical result for Γ -straight line programs. Note that for some applications we need a signature Γ that is part of the input.

THEOREM 3.19. *From a given signature Γ and a Γ -SLP \mathcal{G} , which defines the tree $t = \llbracket \mathcal{G} \rrbracket \in \mathcal{T}_0(\Gamma)$, one can compute in time $O(|\mathcal{G}|)$ a Γ -TSLP \mathcal{H} such that $\llbracket \mathcal{H} \rrbracket^{\hat{\tau}(\Gamma)} = t$, $|\mathcal{H}| \in O(|\mathcal{G}|)$ and $\text{depth}(\mathcal{H}) \in O(\log |t|)$.*

We will prove Theorem 3.19 in Section 3.2. Together with Lemma 3.18, Theorem 3.19 yields the following result.

THEOREM 3.20. *Take a fixed signature Γ and a fixed Γ -algebra \mathcal{A} that has a finite subsumption base. From a given Γ -SLP \mathcal{G} , which defines the derivation tree $t = \llbracket \mathcal{G} \rrbracket \in \mathcal{T}_0(\Gamma)$, one can compute in time $O(|\mathcal{G}|)$ a Γ -SLP \mathcal{H} such that $\llbracket \mathcal{H} \rrbracket^{\mathcal{A}} = \llbracket \mathcal{G} \rrbracket^{\mathcal{A}}$, $|\mathcal{H}| \in O(|\mathcal{G}|)$ and $\text{depth}(\mathcal{H}) \in O(\log |t|)$.*

PROOF. Using Theorem 3.19, we obtain from \mathcal{G} in time $O(|\mathcal{G}|)$ a Γ -TSLP \mathcal{G}' such that $\llbracket \mathcal{G}' \rrbracket^{\hat{\tau}(\Gamma)} = t$, $|\mathcal{G}'| \in O(|\mathcal{G}|)$ and $\text{depth}(\mathcal{G}') \in O(\log |t|)$. From $\llbracket \mathcal{G}' \rrbracket^{\hat{\tau}(\Gamma)} = t = \llbracket \mathcal{G} \rrbracket$, we get $\llbracket \mathcal{G}' \rrbracket^{\mathcal{A}} = \llbracket \mathcal{G} \rrbracket^{\mathcal{A}}$. By Lemma 3.18, we can compute from \mathcal{G}' in time $O(|\mathcal{G}'|) = O(|\mathcal{G}|)$ a Γ -SLP \mathcal{H} of size $O(|\mathcal{G}'|) = O(|\mathcal{G}|)$ and depth $O(\text{depth}(\mathcal{G}')) = O(\log |t|)$ such that $\llbracket \mathcal{H} \rrbracket^{\mathcal{A}} = \llbracket \mathcal{G}' \rrbracket^{\mathcal{A}} = \llbracket \mathcal{G} \rrbracket^{\mathcal{A}}$. \square

Note that Theorem 3.20 is exactly the same statement as Theorem 1.4 from the introduction (which is formulated via circuits instead of straight-line programs).

Remark 3.21. Recall that we made the technical assumption that every element a of \mathcal{A} can be written as $t^{\mathcal{A}}$ for a ground term \mathcal{A} . We can still prove Corollary 3.20 in case \mathcal{A} does not satisfy this assumption: Let \mathcal{B} be the subalgebra of \mathcal{A} that is induced by all elements $t^{\mathcal{A}}$ for $t \in \mathcal{T}(\mathcal{A})$. By Remark 3.15, \mathcal{B} has a finite subsumption base as well. Moreover, for every Γ -SLP \mathcal{G} we obviously have $\llbracket \mathcal{G} \rrbracket^{\mathcal{A}} = \llbracket \mathcal{G} \rrbracket^{\mathcal{B}}$. Hence, Corollary 3.20 applied to the algebra \mathcal{B} yields the statement for \mathcal{A} .

Remark 3.22. Theorem 3.20 only holds for a fixed Γ -algebra, because Lemma 3.18 assumes a fixed Γ -algebra. Nevertheless, there are settings, where we consider a family $\{\mathcal{A}_i \mid i \in I\}$ with the \mathcal{A}_i being Γ_i -algebras. An example is the family of all free monoids Σ^* for a finite alphabet Σ that is part of the input. Under certain assumptions, the statement of Theorem 3.20 can be extended to the uniform setting, where the signature Γ_i ($i \in I$) is part of the input and SLPs are evaluated in the algebra \mathcal{A}_i . First, we have to assume that every symbol $f \in \Gamma_i$ fits into a machine word of the underlying RAM model, which is a natural assumption if the signature Γ_i is part of the input. For the Γ_i -algebras \mathcal{A}_i we need the following assumptions:

- (i) There is a constant r such that the rank of every symbol $f \in \bigcup_{i \in I} \Gamma_i$ is bounded by r .
- (ii) There is a constant c and a finite subsumption base $C(\mathcal{A}_i)$ for every $i \in I$ such that the size of every context $s \in \bigcup_{i \in I} C(\mathcal{A}_i)$ is bounded by c . With the above assumption on the word size of the RAM this ensures that a context $s \in \bigcup_{i \in I} C(\mathcal{A}_i)$ fits into $O(1)$ many machine words.
- (iii) There is a constant time algorithm that computes from a given atomic context s over the signature Γ_i a context $t \in C(\mathcal{A}_i)$ and a substitution ζ such that $\zeta(t)$ and s are equivalent in \mathcal{A}_i .

- (iv) There is a constant time algorithm that takes two contexts s and t over the signature Γ_i such that $s[t]$ is defined, s and t have no common auxiliary variable, and s and t belong to $C(\mathcal{A}_i)$ up to variable renaming, and computes the context $s \cdot t$ (see the first paragraph in the proof of Lemma 3.18) and a substitution ζ such that $\zeta(s \cdot t)$ and $s[t]$ are equivalent in \mathcal{A}_i .

Under these assumptions the construction from the proof of Lemma 3.18 can still be carried out in linear time. Since the statement of Theorem 3.19 holds for a signature Γ that is part of the input, this allows to extend Theorem 3.20 to the setting where the signature Γ_i ($i \in I$) is part of the input. This situation will be encountered for forest algebras (Section 3.3.1) and top dags (Section 3.4).

Before we go into the proof of Theorem 3.19, we first discuss a simple applications of Theorem 3.20 (further applications for certain tree algebras that yield Theorem 1.3 can be found in Sections 3.3 and 3.4). Consider straight-line programs over a semiring \mathcal{A} . Such straight-line programs are also known as arithmetic circuits in the literature. We view addition and multiplication in \mathcal{A} as binary operations. In other words, we consider bounded fan-in arithmetic circuits. We also include arbitrary constants in the algebra \mathcal{A} (this is necessary to build expressions). The following result follows directly from Theorem 3.19 and the fact that every semiring has a finite subsumption base; see Example 3.16.

COROLLARY 3.23. *Let \mathcal{A} be an arbitrary semiring with constants (we neither assume that \mathcal{A} is commutative nor that identity elements with respect to $+$ or \times exist). Given an arithmetic circuit \mathcal{G} over \mathcal{A} such that the corresponding derivation tree t has n nodes, one can compute in time $O(|\mathcal{G}|)$ an arithmetic circuit \mathcal{H} over \mathcal{A} such that $\llbracket \mathcal{H} \rrbracket^{\mathcal{A}} = \llbracket \mathcal{G} \rrbracket^{\mathcal{A}}$, $|\mathcal{H}| \in O(|\mathcal{G}|)$ and $\text{depth}(\mathcal{H}) \in O(\log n)$.*

Theorem 1.2 (balancing of string straight-line programs) can be deduced in the same way from Theorem 3.19 by noting that every free monoid has a finite subsumption base.

3.2 Proof of Theorem 3.19

Those readers that worked through part I of the article (Section 2) will notice that our proof of Theorem 3.19 is very similar to the proof of Theorem 1.2 in Section 2.3. For the following proof, we will use the part I results from Sections 2.1 and 2.2.

Let us fix a signature Γ and a standard Γ -SLP $\mathcal{G} = (\mathcal{V}, \rho, S)$. Let $t = \llbracket \mathcal{G} \rrbracket$ be its derivation tree and $n = |t|$. We view \mathcal{G} also as a DAG $\mathcal{D} := (\mathcal{V}, E)$ with node labels from Γ . The edge relation E contains all edges (X, i, X_i) where $\rho(X)$ is of the form $f(X_1, \dots, X_n)$ and $1 \leq i \leq n$. We can assume that all nodes of the DAG are reachable from the start variable S . All variables from \mathcal{V} also belong to the TSLP \mathcal{H} and produce the same trees in \mathcal{G} and \mathcal{H} . The right-hand side mapping of \mathcal{H} will be denoted by τ .

We start with the symmetric centroid decomposition of the DAG \mathcal{D} , which can be computed in linear time as remarked in Section 2.1. Note that the number $n(\mathcal{D})$ defined in Section 2.1 is the number of leaves of t . Hence, we have $n(\mathcal{D}) \leq n$. Consider a symmetric centroid path

$$(X_0, d_0, X_1), (X_1, d_1, X_2), \dots, (X_{p-1}, d_{p-1}, X_p) \quad (8)$$

in \mathcal{D} , where all X_i belong to \mathcal{V} and $d_i \geq 1$. Thus, for all $0 \leq i \leq p-1$, the right-hand side of X_i in \mathcal{G} has the form

$$\rho(X_i) = f_i(X_{i,1}, \dots, X_{i,d_i-1}, X_{i+1}, X_{i,d_i+1}, \dots, X_{i,n_i}) \quad (9)$$

for $f_i \in \Gamma_{n_i}$, $X_{i,j} \in \mathcal{V}$ for $1 \leq j \leq n_i$, $j \neq d_i$. Figure 4 shows such a path. Note that the variables $X_{i,j}$ do not have to be pairwise different (as Figure 4 might suggest). Also note that the variables $X_{i,j}$ from Equation (9) and all variables in $\rho(X_p)$ belong to other symmetric centroid paths.

Fig. 4. A symmetric centroid path in the proof of Theorem 3.19.

We will introduce $O(p)$ many variables in the TSLP \mathcal{H} to be constructed and the sizes of the corresponding right-hand sides will sum up to $\sum_{i=0}^p |\rho(X_i)| + O(p)$. By summing over all symmetric centroid paths of \mathcal{D} , this yields the size bound $O(|\mathcal{G}|)$ for \mathcal{H} .

Define the ground terms $t_i = \llbracket X_i \rrbracket_{\mathcal{G}}$ for $0 \leq i \leq p$ and $t_{i,j} = \llbracket X_{i,j} \rrbracket_{\mathcal{G}}$ for $0 \leq i \leq p-1$ and $1 \leq j \leq n_i$, $j \neq d_i$. Recall that every variable X_i ($0 \leq i \leq p$) of \mathcal{G} also belongs to \mathcal{H} . For every $0 \leq i \leq p-1$, we introduce a fresh variable Y_i that will evaluate in \mathcal{H} to the context obtained by taking the tree t_i and cutting out the occurrence of the subtree t_p that is reached via the directions $d_i, d_{i+1}, \dots, d_{p-1}$ from the root of t_i . In Figure 4 this context is visualized for $i = 4$ by the red part. Hence, we set

$$\tau(X_i) = Y_i[X_p] \quad (10)$$

for $0 \leq i \leq p$. For X_p , we define

$$\tau(X_p) = \rho(X_p). \quad (11)$$

It remains to come up with right-hand sides such that every Y_i derives to the intended context. For this, we introduce variables Z_i ($0 \leq i \leq p-1$) and define

$$\tau(Z_i) = f_i(X_{i,1}, \dots, X_{i,d_i-1}, x, X_{i,d_i+1}, \dots, X_{i,n_i}) \quad (12)$$

for $0 \leq i \leq p-1$. It remains to add variables and right-hand sides such that every Y_i derives in \mathcal{H} to $Z_i[Z_{i+1}[\dots[Z_{p-1}]\dots]]$. This is basically a string problem: We want to produce an SSLP for all suffixes of $Z_0 Z_1 \dots Z_{p-1}$. This SSLP should have small depth to keep the total depth of the final TSLP bounded by $O(\log n)$. Here, we use Proposition 2.2. For this, we have to define the weights of the variables Z_i . We set $\|Z_i\| = |t_i| - |t_{i+1}|$. We additively extend the weight function to strings over the symbols Z_0, \dots, Z_{p-1} .

Using Proposition 2.2, we can construct in time $O(p)$ a single SSLP \mathcal{I} with the following properties:

- \mathcal{I} has $O(p)$ many variables and all right-hand sides have length at most four,
- \mathcal{I} contains the variables Y_0, \dots, Y_{p-1} , where Y_i produces $Z_i Z_{i+1} \dots Z_{p-1}$ for $0 \leq i \leq p-1$ and

- every path from a variable Y_i to a variable Z_k in the derivation tree of \mathcal{I} has length at most $3 + 2 \log_2 \|Y_i\| - 2 \log_2 \|Z_k\|$ for $i \leq k \leq p - 1$.

Note that $\|Y_i\| = |t_i| - |t_p|$. We finally add to the TSLP \mathcal{H} all right-hand side definitions (10), (11), and (12), and all right-hand side definitions from the SSLP \mathcal{I} . Here, we have to replace a concatenation YZ in a right-hand side of \mathcal{I} by $Y[Z]$.

Concerning the number of introduced variables: For each X_i , we introduce Y_i, Z_i , so $2p$ in total, and the \mathcal{I} is guaranteed to have $O(p)$ variables as well. Summed over all paths this yields $O(n)$. For the size of the rules, each rule introduced in Equation (11) is exactly the rule for X_p (i.e., in Equation (9)) and similarly a rule for Z_i , where $0 \leq i < p$, corresponds to a rule for X_i , in particular, $|\tau(Z_i)| = |\rho(X_i)|$. And so the sum of those productions' sizes is $\sum_{i=0}^p |\rho(X_i)|$. Rules in Equation (10) have size 2 and there are p of them, so their productions' size is $2p$. Last, rules introduced as a translation of rules from \mathcal{I} have the same size as those in \mathcal{I} , which is guaranteed to be $O(p)$. Thus the sum of rules' sizes is at most $\sum_{i=0}^p |\rho(X_i)| + O(p)$. We make the above construction for every symmetric centroid path of \mathcal{G} . Hence, the total size of the TSLP \mathcal{H} is indeed $O(|\mathcal{G}|)$. Moreover, the construction of \mathcal{H} needs linear time. It remains to show that the depth of \mathcal{H} is $O(\log n)$.

First, we consider the symmetric centroid path (8) and a path in \mathcal{H} from a variable X_i ($0 \leq i \leq p$) to a variable $X_{j,k}$ ($i \leq j \leq p - 1$, $1 \leq k \leq n_j$, $k \neq d_j$) or a variable from $\rho(X_p)$. Let us define the weight $\|X\|$ for a variable $X \in \mathcal{V}$ of \mathcal{G} as the size of the tree $\|X\|_{\mathcal{G}}$. A path from X_i to a variable Y in $\rho(X_p)$ has the form $X_i \rightarrow Y$ or $X_i \rightarrow X_p \rightarrow Y$ (since $\tau(X_p) = \rho(X_p)$) and hence has length at most two. Now consider a path from X_i to a variable $X_{j,k}$ with $i \leq j \leq p - 1$. We claim that the length of this path is bounded by $5 + 2 \log_2 \|X_i\| - 2 \log_2 \|X_{j,k}\|$. The path $X_i \xrightarrow{*} X_{j,k}$ has the form

$$X_i \rightarrow Y_i \xrightarrow{*} Z_j \rightarrow X_{j,k},$$

where $Y_i \xrightarrow{*} Z_j$ is a path in \mathcal{I} and hence has length at most $3 + 2 \log_2 \|Y_i\| - 2 \log_2 \|Z_j\|$. Hence, the length of the path is bounded by

$$5 + 2 \log_2 \|Y_i\| - 2 \log_2 \|Z_j\| \leq 5 + 2 \log_2 \|X_i\| - 2 \log_2 \|X_{j,k}\|,$$

since $\|Y_i\| = |t_i| - |t_p| \leq |t_i| = \|X_i\|$ and $\|Z_j\| = |t_j| - |t_{j+1}| \geq |t_{j,k}| = \|X_{j,k}\|$.

Finally, we consider a maximal path in the derivation tree of \mathcal{H} that starts in the root S and ends in a leaf. We can factorize this path as

$$S = X_0 \xrightarrow{*} X_1 \xrightarrow{*} X_2 \xrightarrow{*} \cdots \xrightarrow{*} X_k, \quad (13)$$

where all variables X_i belong to the original Γ -SLP \mathcal{G} , and every subpath $X_i \xrightarrow{*} X_{i+1}$ has the form considered in the last paragraph. The right-hand side of X_k is a single symbol from Γ_0 (such a right-hand side can appear in Equation (11)). In the Γ -SLP \mathcal{G} , we have a corresponding path $X_i \xrightarrow{*} X_{i+1}$ that is contained in a single symmetric centroid path except for the last edge leading to X_{i+1} . By the above consideration, the length of the path (13) is bounded by

$$\sum_{i=0}^{k-1} (5 + 2 \log_2 \|X_i\| - 2 \log_2 \|X_{i+1}\|) \leq 5k + 2 \log_2 \|S\| = 5k + 2 \log_2 n.$$

By the second claim of Lemma 2.1, we have $k \leq 2 \log_2 n$, which shows that the length of the path (13) is bounded by $7 \log_2 n$. This concludes the proof of Theorem 3.19. \square

3.3 Forest Algebras and Forest Straight-line Programs

3.3.1 Forest Algebra. Let us fix a finite set Σ of node labels. In this section, we consider Σ -labelled rooted ordered trees, where “ordered” means that the children of a node are totally ordered. Every node has a label from Σ . In contrast to the trees from Section 3.1.1, we make no rank assumption: The number of children of a node (also called its degree) is *not* determined by its node label. A *forest* is a (possibly empty) sequence of such trees. The size $|v|$ of a forest is the total number of nodes in v . The set of all Σ -labelled forests is denoted by $\mathcal{F}_0(\Sigma)$. Formally, $\mathcal{F}_0(\Sigma)$ can be inductively defined as the smallest set of strings over the alphabet $\Sigma \cup \{ (,) \}$ such that

- $\varepsilon \in \mathcal{F}_0(\Sigma)$ (the empty forest),
- if $u, v \in \mathcal{F}_0(\Sigma)$ then $uv \in \mathcal{F}_0(\Sigma)$, and
- if $u \in \mathcal{F}_0(\Sigma)$ then $a(u) \in \mathcal{F}_0(\Sigma)$ (this is the forest consisting of a single tree whose root is labelled with a).

Let us fix a distinguished symbol $*$ $\notin \Sigma$. The set of forests $u \in \mathcal{F}_0(\Sigma \cup \{*\})$ such that $*$ has a unique occurrence in u and this occurrence is at a leaf node is denoted by $\mathcal{F}_1(\Sigma)$. Elements of $\mathcal{F}_1(\Sigma)$ are called *forest contexts*. Following Reference [9], we define the *forest algebra* as the 2-sorted algebra

$$F(\Sigma) = (\mathcal{F}_0(\Sigma), \mathcal{F}_1(\Sigma), \Theta_{00}, \Theta_{01}, \Theta_{10}, \oplus_0, \oplus_1, (a(*))_{a \in \Sigma}, \varepsilon, *)$$

as follows:

- $\Theta_{ij} : \mathcal{F}_i(\Sigma) \times \mathcal{F}_j(\Sigma) \rightarrow \mathcal{F}_{i+j}(\Sigma)$ ($ij \in \{00, 01, 10\}$) is a horizontal concatenation operator: for $u \in \mathcal{F}_i(\Sigma)$, $v \in \mathcal{F}_j(\Sigma)$ we set $u \Theta_{ij} v = uv$ (i.e., we concatenate the corresponding sequences of trees).
- $\oplus_i : \mathcal{F}_1(\Sigma) \times \mathcal{F}_i(\Sigma) \rightarrow \mathcal{F}_i(\Sigma)$ is a vertical concatenation operator: for $u \in \mathcal{F}_1(\Sigma)$ and $v \in \mathcal{F}_i(\Sigma)$, $u \oplus_i v$ is obtained by replacing in u the unique occurrence of $*$ by v .
- $\varepsilon \in \mathcal{F}_0(\Sigma)$ and $*, a(*) \in \mathcal{F}_1(\Sigma)$ ($a \in \Sigma$) are constants of the forest algebra.

Note that $(\mathcal{F}_0(\Sigma), \Theta_{00}, \varepsilon)$ and $(\mathcal{F}_1(\Sigma), \oplus_1, *)$ are monoids. In the following, we will omit the subscripts i, j in Θ_{ij} and \oplus_i , since they will be always clear from the context. Most of the time, we simply write uv instead of $u \Theta v$, $a(u)$ instead of $a(*) \oplus u$, and a instead of $a(\varepsilon)$. With these abbreviations, a forest $u \in \mathcal{F}(\Sigma)$ can be also viewed as an algebraic expression over the algebra $F(\Sigma)$, which evaluates to u itself (analogously to the free term algebra).

LEMMA 3.24. *Every forest algebra $F(\Sigma)$ has a finite subsumption base.*

PROOF. In the following, we denote by x and y the main variables of sorts $\mathcal{F}_0(\Sigma)$ and $\mathcal{F}_1(\Sigma)$, respectively, and by $\sigma, \sigma_1, \sigma_2, \dots$ (respectively, $\tau, \tau_1, \tau_2, \dots$) auxiliary variables of sorts $\mathcal{F}_0(\Sigma)$ (respectively, $\mathcal{F}_1(\Sigma)$). In the following, subsumption and equivalence of contexts are always meant with respect to the forest algebra $F(\Sigma)$.

Let C be the set of containing the following contexts (see also Figure 5):

- $\tau_1 \oplus x$,
- $\tau_1 \oplus y \oplus \sigma_1$ and $\tau_1 \oplus y \oplus \tau_2$,
- $\tau_1 \oplus (\tau_2 \oplus (\tau_3 \oplus x))$ and $\tau_1 \oplus ((\tau_2 \oplus x) \oplus \tau_3)$,
- $\tau_1 \oplus (\tau_2 \oplus (\tau_3 \oplus y \oplus \sigma_1))$ and $\tau_1 \oplus ((\tau_2 \oplus y \oplus \sigma_1) \oplus \tau_3)$.

A context from point (x) (for $x = a, b, c, d$) will be also called a (x)-context below. First notice that every atomic context is of the form $\tau \oplus x$, $\tau \oplus y$, $y \oplus \sigma$, $y \oplus \tau$, $\sigma \oplus x$, $x \oplus \sigma$, $\sigma \oplus y$, $y \oplus \sigma$, $\tau \oplus x$, or $x \oplus \tau$ (up to variable renaming). Each of these contexts is subsumed by a context in C . For the atomic contexts $\tau \oplus x$, $\tau \oplus y$, $y \oplus \sigma$, $y \oplus \tau$, $\tau \oplus x$, and $x \oplus \tau$ this is obvious. For $\sigma \oplus x$ note that

Fig. 5. The shapes of the contexts in C (proof of Lemma 3.24). Forests and forest contexts are represented by trapezoids. The roots of the forests/forest contexts are located on the top horizontal lines of the trapezoids. Bullet nodes represent occurrences of $*$. Symmetric shapes where the roles of τ_2 and τ_3 exchanged are omitted.

$\sigma \ominus x$ is equivalent to the context $(\sigma \ominus *) \oplus x$, which is subsumed by $\tau_1 \oplus x$. A similar argument also applies to $x \ominus \sigma$, $\sigma \ominus y$ and $y \ominus \sigma$.

Now consider any context $s \in C$. We prove that for any atomic context s' from above, $s'[s]$ is subsumed by some context from C .

Case $\tau \oplus s$ Since s is of the form $s = \tau_1 \oplus s'$ for some s' , the context $\tau \oplus s = \tau \oplus (\tau_1 \oplus s')$ is subsumed by $s \in C$ itself.

Case $s \oplus \sigma$ and $s \oplus \tau$ In this case s must be either the (b)-context $s = \tau_1 \oplus y \oplus \tau_2$, a (c)-context or a (d)-context.

- (1) If $s = \tau_1 \oplus y \oplus \tau_2$, then $s \oplus \sigma$ and $s \oplus \tau$ are subsumed by a (b)-context.
- (2) Assume that s is a (c)-context, say $s = \tau_1 \oplus (\tau_2 \ominus (\tau_3 \oplus x))$. Then $s \oplus \sigma$ is equivalent to $(\tau_1 \oplus ((\tau_2 \oplus \sigma) \ominus \tau_3)) \oplus x$, which is subsumed by $\tau_1 \oplus x$. Moreover, $s \oplus \tau$ is equivalent to $\tau_1 \oplus ((\tau_2 \oplus \tau) \ominus (\tau_3 \oplus x))$, which is subsumed by s itself.
- (3) Assume that s is a (d)-context, say $s = \tau_1 \oplus (\tau_2 \ominus (\tau_3 \oplus y \oplus \sigma_1))$. Firstly, $s \oplus \sigma$ is equivalent to $(\tau_1 \oplus ((\tau_2 \oplus \sigma) \ominus \tau_3)) \oplus y \oplus \sigma_1$, which is subsumed by the context $\tau_1 \oplus x \oplus \sigma_1$. Secondly, $s \oplus \tau$ is equivalent to $\tau_1 \oplus ((\tau_2 \oplus \tau) \ominus (\tau_3 \oplus y \oplus \sigma_1))$, which is subsumed by s itself.

Case $\sigma \ominus s$ and $s \ominus \sigma$ Since s is of the form $s = \tau_1 \oplus s'$ for some s' the context $\sigma \ominus s$ is equivalent to $(\sigma \ominus \tau_1) \oplus s'$, which is subsumed by s itself. The case $s \ominus \sigma$ is similar.

Case $\tau \ominus s$ and $s \ominus \tau$ In this case s must be either the (a)-context or the (b)-context $\tau_1 \oplus y \oplus \sigma_1$. If s is the (a)-context $\tau_1 \oplus x$, then $\tau \ominus s$ is subsumed by the (c)-context $\tau_1 \oplus (\tau_2 \ominus (\tau_3 \oplus x))$. If s is the (b)-context $\tau_1 \oplus y \oplus \sigma_1$, then $\tau \ominus s$ is subsumed by the (d)-context $\tau_1 \oplus (\tau_2 \ominus (\tau_3 \oplus y \oplus \sigma_1))$. The case $s \ominus \tau$ is similar.

By Lemma 3.14, C is a finite subsumption base. \square

Remark 3.25. Similarly to the proof of Lemma 3.24 one can show that for every signature Γ the functional extension $\hat{\mathcal{T}}(\Gamma)$ of the free term algebra $\mathcal{T}(\Gamma)$ has a finite subsumption base as well. Recall from Example 3.17 that the free term algebra $\mathcal{T}(\Gamma)$ has no finite subsumption base if Γ contains a symbol of rank at least one.

3.3.2 Forest Straight-line Programs. A **forest straight-line program over (Σ, \mathcal{F})** (FSLP) is a straight-line program \mathcal{G} over the algebra $\mathcal{F}(\Sigma)$ such that $\llbracket \mathcal{G} \rrbracket^{\mathcal{F}(\Sigma)} \in \mathcal{F}_0(\Sigma)$. Iterated vertical and horizontal concatenations allow to generate forests, whose depth and width is exponential in the size of the FSLP. For an FSLP $\mathcal{G} = (\mathcal{V}, \rho, S)$ and $i \in \{0, 1\}$ we define $\mathcal{V}_i = \{X \in \mathcal{V} \mid \llbracket X \rrbracket^{\mathcal{F}(\Sigma)} \in \mathcal{F}_i(\Sigma)\}$.

Fig. 6. Forest $\llbracket \mathcal{G} \rrbracket^{F(\Sigma)}$ for $n = 2$ from Example 3.26.

Every right-hand side of a standard FSLP \mathcal{G} must have one of the following forms: (i) ε (the empty forest), (ii) $*$, (iii) $a(*)$ for $a \in \Sigma$, (iv) $X \ominus Y$ (for which we write XY) for $X, Y \in \mathcal{V}$ with $X \in \mathcal{V}_0$ or $Y \in \mathcal{V}_0$, or (v) $X \oplus Y$ for $X \in \mathcal{V}_1$ and $Y \in \mathcal{V}$.

Example 3.26. Let $n \in \mathbb{N}$. Consider the (non-standard) FSLP

$$\mathcal{G} = (\{S, X_0, \dots, X_n, Y_0, \dots, Y_n\}, \rho, S)$$

over $\{a, b, c\}$ with ρ defined by $\rho(X_0) = a$, $\rho(X_i) = X_{i-1}X_{i-1}$ for $1 \leq i \leq n$, $\rho(Y_0) = b(X_n * X_n)$, $\rho(Y_i) = Y_{i-1} \oplus Y_{i-1}$ for $1 \leq i \leq n$, and $\rho(S) = Y_n \oplus c$. We have

$$\llbracket \mathcal{G} \rrbracket^{F(\Sigma)} = b(a^{2^n} b(a^{2^n} \dots b(a^{2^n} c a^{2^n}) \dots a^{2^n}) a^{2^n}),$$

where b occurs 2^n many times, see Figure 6 for $n = 2$.

Let us first show that most occurrences of ε and $*$ can be eliminated in an FSLP.

LEMMA 3.27. *From a given FSLP \mathcal{G} with $\llbracket \mathcal{G} \rrbracket^{F(\Sigma)} \neq \varepsilon$ one can compute in linear time an FSLP \mathcal{H} such that $\llbracket \mathcal{G} \rrbracket^{F(\Sigma)} = \llbracket \mathcal{H} \rrbracket^{F(\Sigma)}$, $|\mathcal{H}| \in O(|\mathcal{G}|)$, $\text{depth}(\mathcal{H}) \in O(\text{depth}(\mathcal{G}))$, and \mathcal{H} does not contain occurrences of the constants ε and $*$, except for right-hand sides of the form $a(\varepsilon)$.²*

PROOF. Let $\mathcal{G} = (\mathcal{V}, \rho, S)$. We first construct an equivalent FSLP that does not contain the constant $*$. Let us denote with $\mathcal{V}_* \subseteq \mathcal{V}_1$ the set of all variables $X \in \mathcal{V}_1$ such that $\llbracket X \rrbracket^{F(\Sigma)}$ is of the form $u_\ell * u_r$ for forests $u_\ell, u_r \in \mathcal{F}_0(\Sigma)$. In other words: $*$ occurs at a root position in the forest $\llbracket X \rrbracket^{F(\Sigma)}$. The set \mathcal{V}_* can be easily computed in linear time by a single pass over \mathcal{G} . Every variable $X \in \mathcal{V}_*$ with $\llbracket X \rrbracket^{F(\Sigma)} = u_\ell * u_r$ is replaced in \mathcal{H} by two variables X_ℓ and X_r that produce in \mathcal{H} the forests u_ℓ and u_r , respectively. Every variable $X \in \mathcal{V}_1 \setminus \mathcal{V}_*$ is replaced in \mathcal{H} by three variables X_t, X_ℓ, X_r . Since $X \in \mathcal{V}_1 \setminus \mathcal{V}_*$, $\llbracket X \rrbracket^{F(\Sigma)}$ contains a unique subtree of the form $a(u_\ell * u_r)$. Let us denote with u_t (the top part of u) the forest that is obtained from u by replacing the subtree $a(u_\ell * u_r)$ by $a(*)$. We then will have $\llbracket X_t \rrbracket^{F(\Sigma)} = u_t$, $\llbracket X_\ell \rrbracket^{F(\Sigma)} = u_\ell$, and $\llbracket X_r \rrbracket^{F(\Sigma)} = u_r$. Finally, all variables from \mathcal{V}_0 also belong to \mathcal{H} and produce in \mathcal{H} the same forests as in \mathcal{G} .

It is straight-forward to define the right-hand sides of \mathcal{H} such that the variables indeed produce the desired forests (τ denotes the right-hand side mapping of \mathcal{H}):

- If $\rho(X) = *$, then $\tau(X_\ell) = \tau(X_r) = \varepsilon$.
- If $\rho(X) = a(*)$, then $\tau(X_t) = a(*)$ and $\tau(X_\ell) = \tau(X_r) = \varepsilon$.
- If $\rho(X) = \varepsilon$ or $\rho(X) = YZ$ with $X, Y, Z \in \mathcal{V}_0$, then $\tau(X) = \rho(X)$.
- If $\rho(X) = YZ$ with $X, Y \in \mathcal{V}_*$ and $Z \in \mathcal{V}_0$, then $\tau(X_\ell) = Y_\ell$ and $\tau(X_r) = Y_r Z$, and analogously for $X, Z \in \mathcal{V}_*$ and $Y \in \mathcal{V}_0$.
- If $\rho(X) = YZ$ with $X, Y \in \mathcal{V}_1 \setminus \mathcal{V}_*$ and $Z \in \mathcal{V}_0$, then $\tau(X_\ell) = Y_\ell$, $\tau(X_r) = Y_r$, and $\tau(X_t) = Y_t Z$, and analogously for $X, Z \in \mathcal{V}_1 \setminus \mathcal{V}_*$ and $Y \in \mathcal{V}_0$.

²Constants $a(*)$ are allowed as well. Formally, $a(*)$ is a constant symbol that is interpreted by the forest context $a(*)$.

- If $\rho(X) = Y \oplus Z$ with $X, Z \in \mathcal{V}_0$ and $Y \in \mathcal{V}_*$, then $\tau(X) = Y_\ell Z Y_r$.
- If $\rho(X) = Y \oplus Z$ with $X, Z \in \mathcal{V}_0$ and $Y \in \mathcal{V}_1 \setminus \mathcal{V}_*$, then $\tau(X) = Y_t \oplus (Y_\ell Z Y_r)$.
- If $\rho(X) = Y \oplus Z$ with $X, Y, Z \in \mathcal{V}_*$, then $\tau(X_\ell) = Y_\ell Z_\ell$ and $\tau(X_r) = Z_r Y_r$.
- If $\rho(X) = Y \oplus Z$ with $Y \in \mathcal{V}_*$ and $X, Z \in \mathcal{V}_1 \setminus \mathcal{V}_*$, then $\tau(X_t) = Y_\ell Z_t Y_r$, $\tau(X_\ell) = Z_\ell$, and $\tau(X_r) = Z_r$.
- If $\rho(X) = Y \oplus Z$ with $Z \in \mathcal{V}_*$ and $X, Y \in \mathcal{V}_1 \setminus \mathcal{V}_*$, then $\tau(X_t) = Y_t$, $\tau(X_\ell) = Y_\ell Z_\ell$, and $\tau(X_r) = Z_r Y_r$.
- If $\rho(X) = Y \oplus Z$ with $X, Y, Z \in \mathcal{V}_1 \setminus \mathcal{V}_*$, then $\tau(X_t) = Y_t \oplus (Y_\ell Z_t Y_r)$, $\tau(X_\ell) = Z_\ell$, and $\tau(X_r) = Z_r$.

Note that all right-hand sides of the new FSLP have constant length. Variables X such that $\tau(X)$ is a variable can be eliminated.

Let us finally eliminate occurrences of the constant ε , except for right-hand sides of the form $a(\varepsilon)$. Let us take an FSLP $\mathcal{G} = (\mathcal{V}, \rho, S)$ with $\llbracket \mathcal{G} \rrbracket^{\text{F}(\Sigma)} \neq \varepsilon$ and that does not contain occurrences of the constant $*$. Let $\mathcal{V}_\varepsilon = \{X \in \mathcal{V}_0 \mid \llbracket X \rrbracket^{\text{F}(\Sigma)} = \varepsilon\}$. Note that $S \notin \mathcal{V}_\varepsilon$. The set \mathcal{V}_ε can be easily computed in linear time by a single pass over \mathcal{G} . We construct an equivalent FSLP \mathcal{H} that neither contains $*$ nor ε , except for right-hand sides of the form $a(*)$ and $a(\varepsilon)$. All variables from \mathcal{G} are also contained in \mathcal{H} , except for variables in \mathcal{V}_ε . For every variable $X \in \mathcal{V}_1$, \mathcal{H} also contains a copy X_ε that produces $\llbracket X \rrbracket^{\text{F}(\Sigma)} \oplus \varepsilon$. The right-hand side mapping τ of \mathcal{H} is defined as follows:

- If $\rho(X) = a(*)$ then $\tau(X) = a(*)$ and $\tau(X_\varepsilon) = a(\varepsilon)$.
- If $\rho(X) = \varepsilon$ then X does not belong to \mathcal{H} .
- If $\rho(X) = YZ$ with $Y, Z \in \mathcal{V}_\varepsilon$ then $X \in \mathcal{V}_\varepsilon$ does not belong to \mathcal{H} .
- If $\rho(X) = YZ$ or $\rho(X) = ZY$ with $Y \in \mathcal{V}_\varepsilon$ and $Z \in \mathcal{V}_0 \setminus \mathcal{V}_\varepsilon$ then $\tau(X) = Z$.
- If $\rho(X) = YZ$ with $Y, Z \in \mathcal{V}_0 \setminus \mathcal{V}_\varepsilon$ then $\tau(X) = YZ$.
- If $\rho(X) = YZ$ or $\rho(X) = ZY$ with $Y \in \mathcal{V}_\varepsilon$ and $X, Z \in \mathcal{V}_1$ then $\tau(X) = Z$ and $\tau(X_\varepsilon) = Z_\varepsilon$.
- If $\rho(X) = YZ$ with $Y \in \mathcal{V}_0 \setminus \mathcal{V}_\varepsilon$ and $X, Z \in \mathcal{V}_1$ then $\tau(X) = YZ$ and $\tau(X_\varepsilon) = YZ_\varepsilon$, and similarly if $Z \in \mathcal{V}_0 \setminus \mathcal{V}_\varepsilon$ and $X, Y \in \mathcal{V}_1$.
- If $\rho(X) = Y \oplus Z$ with $X, Y, Z \in \mathcal{V}_1$ then $\tau(X) = Y \oplus Z$ and $\tau(X_\varepsilon) = Y \oplus Z_\varepsilon$.
- If $\rho(X) = Y \oplus Z$ with $Y \in \mathcal{V}_1$ and $Z \in \mathcal{V}_\varepsilon$ then $\tau(X) = Y_\varepsilon$.
- If $\rho(X) = Y \oplus Z$ with $Y \in \mathcal{V}_1$ and $Z \in \mathcal{V}_0 \setminus \mathcal{V}_\varepsilon$ then $\tau(X) = Y \oplus Z$.

As in the previous case, variables X such that $\tau(X)$ is a variable, can be eliminated. Note that the construction does not introduce new occurrences of $*$. All variables from $\mathcal{V} \setminus \mathcal{V}_\varepsilon$ produce the same forest in \mathcal{G} and \mathcal{H} , which implies $\llbracket \mathcal{G} \rrbracket^{\text{F}(\Sigma)} = \llbracket \mathcal{H} \rrbracket^{\text{F}(\Sigma)}$. Finally note that both constructions increase the size and depth of the FSLP only by a constant factor. \square

COROLLARY 3.28. *Given a finite alphabet Σ and an FSLP \mathcal{G} over the forest algebra $\text{F}(\Sigma)$ defining the forest $u = \llbracket \mathcal{G} \rrbracket^{\text{F}(\Sigma)}$, one can compute in time $O(|\mathcal{G}|)$ an FSLP \mathcal{H} such that $\llbracket \mathcal{H} \rrbracket^{\text{F}(\Sigma)} = u$, $|\mathcal{H}| \in O(|\mathcal{G}|)$ and $\text{depth}(\mathcal{H}) \in O(\log |u|)$.*

PROOF. The case $u = \varepsilon$ is trivial. Let us now assume that $u \neq \varepsilon$. We first apply Lemma 3.27 and construct from \mathcal{G} in linear time an equivalent FSLP \mathcal{G}' that does not contain occurrences of the constants $*$ and ε , except for right-hand sides of the form $a(\varepsilon)$. This ensures that the derivation tree $t = \llbracket \mathcal{G}' \rrbracket$ has size $O(|u|)$. The size and depth of \mathcal{G}' are linearly bounded in the size and depth, respectively, of \mathcal{G} . By Lemma 3.24, we can apply Theorem 3.20 in order to get the FSLP \mathcal{H} with the desired properties for the situation where the alphabet Σ is fixed. For the situation where Σ is part of the input one has to use Remark 3.22. The arguments are analogous to the proof of Theorem 1.2. Note in particular that the subsumption base from the proof of Lemma 3.24 does not depend on the alphabet Σ of the forest algebra $\text{F}(\Sigma)$. \square

Remark 3.29. Using Remark 3.25 one can show the following variant of Corollary 3.28: Take a fixed signature Γ . From a given Γ -TSLP \mathcal{G} defining the tree $t = \llbracket \mathcal{G} \rrbracket^{\hat{\mathcal{T}}(\Gamma)}$, one can compute in time $O(|\mathcal{G}|)$ a Γ -TSLP \mathcal{H} such that $\llbracket \mathcal{H} \rrbracket^{\hat{\mathcal{T}}(\Gamma)} = t$, $|\mathcal{H}| \in O(|\mathcal{G}|)$ and $\text{depth}(\mathcal{H}) \in O(\log |t|)$. In other words, Γ -TSLPs can be balanced with a linear size increase. Note that this is a much stronger statement than Theorem 3.19, which states that a Γ -SLP can be balanced into an equivalent Γ -TSLP with a linear size increase. However, the above balancing result for Γ -TSLPs finally uses the weaker Theorem 3.19 in its proof. We have to assume a fixed signature Γ in the above argument, since the size of the contexts in a finite subsumption for $\hat{\mathcal{T}}(\Gamma)$ depends on the maximal rank of the symbols in Γ .

Alternatively, the balancing result for Γ -TSLPs can be deduced from the corresponding balancing result for FSLPs (Corollary 3.28): A given Γ -TSLP \mathcal{G} can be directly translated into an FSLP \mathcal{G}_1 for the tree $\llbracket \mathcal{G} \rrbracket^{\hat{\mathcal{T}}(\Gamma)}$. The size of \mathcal{G}_1 is $O(|\mathcal{G}|)$. Using Corollary 3.28 one can compute from \mathcal{G}_1 a balanced FSLP \mathcal{G}_2 of size $O(|\mathcal{G}_1|)$. Finally, the FSLP \mathcal{G}_2 can be easily transformed back into a Γ -TSLP of size $O(r \cdot |\mathcal{G}_2|)$, where r is the maximal rank of a symbol in Γ . For this one has to eliminate horizontal concatenations in the FSLP. Since we assumed Γ to be a fixed signature, r is a constant.

3.4 Cluster Algebras and Top Dags

FSLPs are very similar to *top dags* that were introduced in Reference [7] and further studied in Reference [4, 13, 22]. In fact, top dags can be defined in the same way as FSLPs, one only has to slightly change the two concatenation operations \ominus and \oplus , which yields the so-called cluster algebra defined below.

Let us fix an alphabet Σ of node labels and define for $a \in \Sigma$ the set $\mathcal{K}_a(\Sigma) = \{a(u) \mid u \in \mathcal{F}_0(\Sigma) \setminus \{\epsilon\}\}$. Note that $\mathcal{K}_a(\Sigma)$ consists of unranked Σ -labelled trees of size at least two, where the root is labeled with a . Elements of $\mathcal{K}_a(\Sigma)$ (for any a) are also called *clusters of rank 0*. For $a, b \in \Sigma$ let $\mathcal{K}_{ab}(\Sigma)$ be the set of all trees $t \in \mathcal{K}_a(\Sigma)$ together with a distinguished b -labelled leaf of t , which is called the *bottom boundary node* of t . Elements of $\mathcal{K}_{ab}(\Sigma)$ (for any a, b) are called *clusters of rank one*. The root node of a cluster t (of rank zero or one) is called the *top boundary node* of t . When writing a cluster of rank one, we underline the bottom boundary node. For instance $a(bc(\underline{ba}))$ is an element of $\mathcal{K}_{ab}(\Sigma)$. An *atomic cluster* is of the form $a(b)$ or $a(\underline{b})$ for $a, b \in \Sigma$.

We define the *cluster algebra* $\mathbf{K}(\Sigma)$ as an algebra over a $(\Sigma \cup \Sigma^2)$ -sorted signature. The universe of sort $a \in \Sigma$ is $\mathcal{K}_a(\Sigma)$ and the universe of sort $ab \in \Sigma^2$ is $\mathcal{K}_{ab}(\Sigma)$. The operations of $\mathbf{K}(\Sigma)$ are the following:

- There are $|\Sigma| + 2|\Sigma|^2$ many horizontal merge operators; we denote all of them with the same symbol \ominus . Their domains and ranges are specified by $\ominus : \mathcal{K}_a(\Sigma) \times \mathcal{K}_a(\Sigma) \rightarrow \mathcal{K}_a(\Sigma)$, $\ominus : \mathcal{K}_a(\Sigma) \times \mathcal{K}_{ab}(\Sigma) \rightarrow \mathcal{K}_{ab}(\Sigma)$, and $\ominus : \mathcal{K}_{ab}(\Sigma) \times \mathcal{K}_a(\Sigma) \rightarrow \mathcal{K}_{ab}(\Sigma)$, where $a, b \in \Sigma$. All of these merge operators are defined by $a(u) \ominus a(v) = a(uv)$, where sorts of the clusters u, v must match the input sorts for one of the merge operators.
- There are $|\Sigma|^2 + |\Sigma|^3$ many vertical merge operators; we denote all of them with the same symbol \oplus . Their domains and ranges are specified by $\oplus : \mathcal{K}_{ab}(\Sigma) \times \mathcal{K}_b(\Sigma) \rightarrow \mathcal{K}_a(\Sigma)$ and $\oplus : \mathcal{K}_{ab}(\Sigma) \times \mathcal{K}_{bc}(\Sigma) \rightarrow \mathcal{K}_{ac}(\Sigma)$ for $a, b, c \in \Sigma$. For clusters $s \in \mathcal{K}_{ab}(\Sigma)$ and $t \in \mathcal{K}_b(\Sigma) \cup \mathcal{K}_{bc}(\Sigma)$, we obtain $s \oplus t$ by replacing in s the bottom boundary node by t . For instance,

$$a(bc(\underline{ba})) \oplus b(ac) = a(bc(b(ac)a)).$$

- The atomic clusters $a(b)$ and $a(\underline{b})$ are constants of the cluster algebra.

In the following, we just write \mathcal{K}_a and \mathcal{K}_{ab} for $\mathcal{K}_a(\Sigma)$ and $\mathcal{K}_{ab}(\Sigma)$, respectively. A *top dag* over Σ is an SLP \mathcal{G} over the algebra $\mathbf{K}(\Sigma)$ such that $\llbracket \mathcal{G} \rrbracket^{\mathbf{K}(\Sigma)}$ is a cluster of rank zero.³ In our terminology, cluster straight-line program would be a more appropriate name, but we prefer to use the original term “top dag.”

Example 3.30. Consider the top dag $\mathcal{G} = (\{S, X_0, \dots, X_n, Y_0, \dots, Y_n\}, \rho, S)$ with $\rho(X_0) = b(a)$, $\rho(X_i) = X_{i-1} \ominus X_{i-1}$ for $1 \leq i \leq n$, $\rho(Y_0) = X_n \ominus b(\underline{b}) \ominus X_n$, $\rho(Y_i) = Y_{i-1} \oplus Y_{i-1}$ for $1 \leq i \leq n$, and $\rho(S) = Y_n \oplus b(c)$. We have

$$\llbracket \mathcal{G} \rrbracket^{\mathbf{K}(\Sigma)} = b(a^{2^n} b(a^{2^n} \dots b(a^{2^n} b(c) a^{2^n}) \dots a^{2^n}) a^{2^n}),$$

where b occurs $2^n + 1$ many times.

In Reference [16] it was shown that from a top dag \mathcal{G} one can compute in linear time an equivalent FSLP of size $O(|\mathcal{G}|)$. Vice versa, from an FSLP \mathcal{H} for a tree $t \in \mathcal{C}_a$ (for some $a \in \Sigma$) one can compute in time $O(|\Sigma| \cdot |\mathcal{H}|)$ an equivalent top dag of size $O(|\Sigma| \cdot |\mathcal{H}|)$. The additional factor $|\Sigma|$ in the transformation from FSLPs to top dags is unavoidable; see Reference [16] for an example.

LEMMA 3.31. *Every cluster algebra $\mathbf{K}(\Sigma)$ has a finite subsumption base.*

PROOF. The proof is similar to the proof of Lemma 3.24. Let the set C contain the following contexts, where in each context, each of the auxiliary variables $\sigma_1, \sigma_2, \sigma_3, \tau_1, \tau_2, \tau_3, \tau_4$ can be also missing (this is necessary, since in the cluster algebra, the merge operations have no neutral elements). The main variable x and the auxiliary variables $\sigma_1, \sigma_2, \sigma_3$ must have sorts from Σ (rank zero), whereas the main variable y and the auxiliary variables $\tau_1, \tau_2, \tau_3, \tau_4$ must have sorts from $\Sigma\Sigma$ (rank one). The concrete sorts must be chosen such that all horizontal and vertical merge operations are defined.

- (a) $\tau_1 \oplus (\sigma_1 \ominus x \ominus \sigma_2)$
- (b) $\tau_1 \oplus (\sigma_1 \ominus y \ominus \sigma_2) \oplus \sigma_3$
- (c) $\tau_1 \oplus (\sigma_1 \ominus y \ominus \sigma_2) \oplus \tau_2$
- (d) $\tau_4 \oplus (\tau_3 \ominus (\tau_1 \oplus (\sigma_1 \ominus x \ominus \sigma_2)))$
- (e) $\tau_4 \oplus ((\tau_1 \oplus (\sigma_1 \ominus x \ominus \sigma_2)) \ominus \tau_3)$
- (f) $\tau_4 \oplus (\tau_3 \ominus (\tau_1 \oplus (\sigma_1 \ominus y \ominus \sigma_2) \oplus \sigma_3))$
- (g) $\tau_4 \oplus ((\tau_1 \oplus (\sigma_1 \ominus y \ominus \sigma_2) \oplus \sigma_3) \ominus \tau_3)$

Note that these forms are very similar to the forms (a)–(g) for forest algebras from the proof of Lemma 3.24. Only the variables σ_1 and σ_2 that are horizontally merged with x (respectively, y) are new.

Figure 7 shows the shapes of the above contexts. Let us explain the intuition behind these shapes. Take a cluster s (of rank zero or one) and cut out from s a subcluster x of rank zero or a subcluster y of rank one. We do not give a formal definition of subclusters (see Reference [7]), but roughly speaking this means that x (respectively, y) is a cluster that occurs somewhere in s . In Figure 7, these subclusters are the red triangles. The part of s that does not belong to the subcluster x (respectively, y) can be partitioned into finitely many subclusters, and these are the white triangles in Figure 7.

Using Lemma 3.14, we can show that C is a finite subsumption base for the cluster algebra $\mathbf{K}(\Sigma)$. The atomic clusters are $\tau \ominus x, \sigma \ominus x, \sigma \ominus y, x \ominus \tau, x \ominus \sigma, y \ominus \sigma, \tau \oplus x, \tau \oplus y, x \oplus \tau, x \oplus \sigma$ (where x

³Note that the definition of a top dag in Reference [7] refers to the outcome of a particular top dag construction. In other words: For every tree t a very specific SLP over the cluster algebra is constructed and this SLP is called the top dag of t . Here, as in Reference [16], we call any SLP over the cluster algebra a top dag.

Fig. 7. The shapes of the contexts in C (proof of Lemma 3.31). Bullet nodes represent boundary nodes. Symmetric shapes where τ_3 is to the right of τ_1 are omitted.

Fig. 8. Two example cases from the proof of Lemma 3.31.

and σ have sorts from Σ and y and τ have sorts from $\Sigma\Sigma$). Each of these atomic contexts belongs to C up to renaming of auxiliary variables. For this it is important that every context from the above list (a)–(g), where some of the auxiliary variables are omitted, belongs to C as well.

Let us now consider a context $s'[s]$, where $s \in C$ and s' is atomic. We have to show that $s'[s]$ is subsumed in $K(\Sigma)$ by a context from C . The case distinction is very similar to the proof of Lemma 3.24. Two examples are shown in Figure 8. The left figure shows the case $s = \tau_1 \oplus (\sigma_1 \ominus y \ominus \sigma_2) \oplus \sigma_3$ and $s' = \tau \ominus x$. In this case $s'[s] = \tau \ominus (\tau_1 \oplus (\sigma_1 \ominus y \ominus \sigma_2) \oplus \sigma_3)$ is subsumed in $K(\Sigma)$ by $\tau_3 \ominus (\tau_1 \oplus (\sigma_1 \ominus y \ominus \sigma_2) \oplus \sigma_3)$ (the latter is obtained from the context in (f) by removing τ_4).

Figure 8 on the right shows the case $s = \tau_4 \oplus (\tau_3 \ominus (\tau_1 \oplus (\sigma_1 \ominus y \ominus \sigma_2) \oplus \sigma_3))$ and $s' = y \oplus \sigma$. We have $s'[s] = \tau_4 \oplus ((\tau_3 \oplus \sigma) \ominus (\tau_1 \oplus (\sigma_1 \ominus y \ominus \sigma_2) \oplus \sigma_3))$, which is equivalent in $K(\Sigma)$ to $(\tau_4 \ominus ((\tau_3 \oplus \sigma) \ominus \tau_1)) \oplus (\sigma_1 \ominus y \ominus \sigma_2) \oplus \sigma_3$. The latter context is subsumed in $K(\Sigma)$ by $\tau_1 \oplus (\sigma_1 \ominus y \ominus \sigma_2) \oplus \sigma_3 \in C$. \square

We can now show the main result for top dags:

COROLLARY 3.32. *Given a finite alphabet Σ and a top dag \mathcal{G} over the cluster algebra $K(\Sigma)$ producing the tree $t = \llbracket \mathcal{G} \rrbracket^{K(\Sigma)}$, one can compute in time $O(|\mathcal{G}|)$ a top dag \mathcal{H} for t of size $O(|\mathcal{G}|)$ and depth $O(\log |t|)$.*

PROOF. Note that in the derivation tree $\llbracket \mathcal{G} \rrbracket$ of a top dag \mathcal{G} , all leaves are labelled with atomic clusters and all internal nodes have rank two. Hence, the size of the derivation tree $\llbracket \mathcal{G} \rrbracket$ is linearly

bounded in the size of the generated tree $\llbracket \mathcal{G} \rrbracket^{K(\Sigma)}$ (in the forest algebra, we needed Lemma 3.27 to enforce this property). For the case of a fixed alphabet Σ , the statement of the corollary follows from Lemma 3.31 and Theorem 3.20 analogously to Corollary 3.28 for FSLPs. For the general case of a variable-size alphabet Σ , we have to use again Remark 3.22. As for SSLPs and FSLPs, we need the natural assumption that symbols from the input alphabet fit into a single machine word of the RAM. All operations from a cluster algebra have rank zero and two, and the subsumption base C from the proof of Lemma 3.31 has the property that every context $s \in \Sigma$ has constant size. In contrast to free monoids and forest algebras, the subsumption base depends on the alphabet Σ . Basically, we need to choose the sorts of the variables $x, y, \tau_1, \tau_2, \tau_3, \sigma_1, \sigma_2, \sigma_3, \sigma_4$ in each of the contexts from C . This implies that every context $s \in C$ can be represented by a constant number of symbols from Σ and hence can be stored in a constant number of machine words. The constant time algorithms from point (iii) and (iv) from Remark 3.22 make a constant number of comparisons between the Σ -symbols representing the input contexts. \square

In Reference [20] top dags have been used for compressed RMQs. It is well known that for a string s of integers one can reduce RMQs to lowest common ancestor queries on the Cartesian tree corresponding to s . Two compressed data structures for answering RMQs for s are proposed in Reference [20]: One is based on an SSLP for s (we commented on it already in Section 2.4), the other one uses a top dag for the Cartesian tree corresponding to s . The following result has been shown, see Reference [20, Corollary 1.4]:

Given a string s of length n over an alphabet of σ many integers, let m_{opt} denote the size of a smallest SSLP for s . There is a top dag \mathcal{G} for the Cartesian tree corresponding to s of size $|\mathcal{G}| \leq \min(O(n/\log n), O(m_{\text{opt}} \cdot \log n \cdot \sigma))$, and there is a data structure of size $O(|\mathcal{G}|)$ that answers range minimum queries on s in time $O(\log \sigma \cdot \log n)$.

As the time bound $O(\log \sigma \cdot \log n)$ comes from the height of the constructed top dag, using Corollary 3.32 we can enforce the bound $O(\log n)$ on the height of the constructed top dag and ensure that the transformation can be applied to any input SSLP. This yields the following improvement of the result of Reference [20].

THEOREM 3.33. *Given an SSLP of size m generating a string s of length n over an alphabet of σ many integers one can compute a top dag \mathcal{G} for the Cartesian tree corresponding to s of size $|\mathcal{G}| \leq \min(O(n/\log n), O(m \cdot \sigma))$ and depth $O(\log n)$, and there is a data structure of size $O(|\mathcal{G}|)$ that answers RMQs on s in time $O(\log n)$. If m_{opt} denotes the size of a smallest SSLP generating s , then using Rytter's algorithm, we can assume that $m \leq O(m_{\text{opt}} \cdot \log n)$.*

4 OPEN PROBLEMS

For SSLPs one may require a strong notion of balancing. Let us say that an SSLP \mathcal{G} is c -balanced if (i) the length of every right-hand side is at most c and (ii) if a variable Y occurs in $\rho(X)$ then $|\llbracket Y \rrbracket_{\mathcal{G}}| \leq |\llbracket X \rrbracket_{\mathcal{G}}|/2$. It is open, whether there is a constant c such that for every SSLP of size m there exists an equivalent c -balanced SSLP of size $O(m)$.

Another important open problem is whether the query time bound in Theorem 1.1 (random access to grammar-compressed strings) can be improved from $O(\log n)$ to $O(\log n / \log \log n)$. If we allow space $O(m \cdot \log^\epsilon n)$ (for any small $\epsilon > 0$), then such an improvement is possible by Corollary 2.4, but it is open whether query time $O(\log n / \log \log n)$ can be achieved with space $O(m)$. By the lower bound from Reference [39] this would be an optimal random-access data structure for grammar-compressed strings.
